Abstract

Countries restrict exports to rivals to gain geopolitical leverage. Because such restrictions apply only to the target, the covered goods can still reach it through third countries, a practice known as transshipment. We study how much transshipment reduces the cost of the EU's export bans to Russia after the full-scale invasion of Ukraine. Combining Russian customs records, which report each good's origin and the country through which it reached Russia, with new data on the bans, we find that 20–30% of pre-war imports of banned EU goods kept arriving through 2024. Hence, rather than becoming prohibitive, trade costs for the median banned good rose by only 69%. In a general equilibrium model featuring endogenous transshipment, we show that Russia's real-income losses would be 32% higher without transshipment. Transshipment also changes which goods are most effective to ban and how much countries add by joining the coalition.

1 Introduction

Governments increasingly turn trade policy against their rivals (Clayton et al. 2025; Mohr and Trebesch 2025). Since 2020, discriminatory trade measures have been introduced at roughly five times the pre-2015 rate (Global Trade Alert 2026). How much a trade restriction costs its target, and hence the leverage it gives the country imposing it, depends on how easily the target can make up for what it can no longer buy directly. The literature has long focused on how a targeted country substitutes toward other trading partners, known as trade diversion (Clayton et al. 2026; Hirschman 1945; Liu and Yang 2025). However, these restrictions apply, by design, only to the target and are often high or even prohibitive, creating incentives to route restricted goods through third countries that can trade cheaply with both sides.[1] We ask how much this practice, known as transshipment, reduces the cost of trade restrictions to their targets, and what the countries imposing them can do to limit it.

We study the export bans that the European Union (EU) imposed on Russia after its full-scale invasion of Ukraine in 2022, a setting in which transshipment is both valuable and feasible. By the end of 2024, the bans covered 79% of Russia's pre-war imports from the EU. Because 18 other countries, including the United States and Japan, imposed similar restrictions, Russia cannot easily buy many of these goods from other suppliers.[2] Although the bans prohibit indirect as well as direct exports, the EU has little reach over resales in third countries. Several of these countries, such as Türkiye and the United Arab Emirates (UAE), trade cheaply with both the EU and Russia, which makes them natural hubs for banned goods.

Whereas existing studies infer transshipment from anomalies in trade flows (e.g., Fisman et al. 2008; Freund 2025; Iyoha et al. 2025), we observe it directly by linking Russian customs declarations with granular data on the EU export bans. The customs declarations report for each import where the good was made, where its seller was based, and which firm shipped it from which country.[3] Some bans cover all goods in a tariff line, the most detailed product category in trade data. Others cover only certain variants of a good within a tariff line, such as those with potential military uses. Unlike the common practice of classifying products only as sanctioned or not (e.g., Egorov et al. 2025*a*; Hausmann

[1] Felbermayr et al. (2019) show that, in 2014, differences in external tariffs within trade agreements were rarely large enough to make such routes profitable.

[2] Appendix B.1 discusses the coalition in more detail.

[3] A natural concern is whether Russian customs records remain reliable after the invasion. Three pieces of evidence suggest they do: the records closely match the exports reported by Russia's non-sanctioning trading partners, by sector and partner country; Western authorities have used them to corroborate charges for sanctions violations; and the only documented manipulation consisted of no longer recording certain imports rather than falsifying their origin. Russia also has little reason to conceal these imports, having legalized in 2022 the parallel import of goods brought in without the brand owner's consent (Section 2.5).

et al. 2024), our novel ban data record, for every tariff line, when it first becomes partially or fully banned and when a partial ban is extended to a full one. Because the customs declarations do not distinguish variants within a tariff line, we define transshipment as Russian imports of EU-origin products that are fully banned at the time of import.[4] The measure is a lower bound, because banned variants in partially banned lines are likely transshipped as well. Their imports cannot be separated from those of legal variants, however, so counting all EU-origin imports in these lines yields an upper bound. Together, the two sources allow us to measure how much is transshipped, through which routes, and by whom.

Russian imports of banned EU goods fell to 20 to 30% of their pre-war level, whereas bans without any transshipment would have stopped them entirely, the equivalent of an infinite increase in trade costs. Because the goods still arrive, the actual increase must be finite, and gravity lets us infer its size from how much the imports fell. To isolate the part of the fall caused by the bans, we use a triple-differences design that compares imports of banned EU products with imports of the same products from countries outside the coalition and with imports of never-banned EU products. The first comparison absorbs changes in Russian demand, the second shocks to all trade between the EU and Russia, such as financial sanctions. Relative to both, imports of fully banned EU goods fall by 85%, with no pre-trends. For the median fully banned product from an EU country, the product-level trade elasticities of Fontagné et al. (2022) translate this decline into an increase in trade costs of 69% relative to direct imports before the war.

90% of transshipped goods enter Russia through hubs outside the EU, mainly Türkiye and Belarus, where firms can cheaply act as intermediaries between EU producers and Russian buyers. Firms that specialize in buying and reselling goods took on a larger role in Russian imports of fully banned EU goods, with their share of declarations rising by 15 percentage points.[5] As Ahn et al. (2011) show, such firms lower the cost of reaching markets that are expensive to serve directly, which helps explain why routing banned goods through hubs costs so little. From late 2022 to autumn 2024, the EU introduced a series of measures aimed at curbing transshipment.[6] These measures barely changed the bans' effect on Russian imports of fully banned EU goods, but they did change the paperwork: by the end of 2024, Russian imports of banned goods shipped from the EU

[4] We aggregate to the 6-digit level of the Harmonized System, the most disaggregated level that is comparable across countries.

[5] We count a declaration as theirs if they are named as the sender, the consignor on the transport document. The increase is relative to never-banned products and non-coalition origins. Following Ahn et al. (2011), we identify these firms by words such as "trading" or "import export" in their names.

[6] From February 2023, the EU banned the transit of a growing set of banned goods through Russia, and from March 2024, it required exporters of the most sensitive goods to include "no re-export to Russia" clauses in their contracts.

and officially sold to the Russian buyer by an EU firm had fallen by 98%, so that on paper EU firms complied almost perfectly.

To quantify how much transshipment weakens the bans, we add it to a general-equilibrium Eaton–Kortum model (Eaton and Kortum 2002) with many products (Costinot et al. 2012) and nested demand, so that Russia can protect its spending on military-relevant and other critical goods. As in Foellmi et al. (2024), trade costs satisfy the triangle inequality: the trade cost between two countries cannot exceed the cost of the cheapest route through a third. A ban on direct exports therefore raises the trade cost of a banned EU good only to the cost of its cheapest route through a hub.[7] The cost of such a route has two components: the ordinary trade costs of its two legs and a hub-specific cost of redirecting banned goods. We infer ordinary trade costs from pre-war trade flows, so they include every barrier, not only observable ones such as distance and tariffs. The hub-specific cost is lower in more capable hubs, for example where local firms act as intermediaries or customs unions limit border checks, as between Belarus and Russia or the EU and Türkiye. Together, the two components determine which hub Russia uses. We define Russia's transshipment gain as how much smaller its real-income loss is than when it cannot buy banned goods through hubs and must rely on trade diversion, as existing work quantifying sanctions assumes (e.g., Chowdhry et al. 2024; Flach et al. 2024; Hausmann et al. 2024).

The model's transshipment parameters come directly from the data. We infer ordinary trade costs for each 6-digit product from 2019 trade flows, and our ban data determine which products are covered.[8] While ordinary trade costs alone already predict four of the five largest hubs in the customs data, they understate the roles of Türkiye, Belarus, and the UAE and imply a much smaller decline in banned imports than the 85% we estimate. The hubs Russia uses in the 2024 customs declarations and the estimated decline identify the hub-specific costs that close both gaps. How much more Russia uses a hub in the 2024 customs data than its ordinary trade costs predict reveals its relative capability, and the decline pins down the average. The model fits the data well, including untargeted moments such as the hubs used by other coalition countries.

Transshipment substantially lowers what the bans cost Russia, as its real-income loss of 1.26% would be 32% larger without it. Russia's access to military-relevant goods falls by 3.6%, much more than its real income, and by 4.0% without transshipment. If routes through hubs cost only their ordinary trade costs, the loss would be 54% smaller than with observed transshipment. Transshipping banned goods is thus costly through any

[7] Russia buys each banned good through its cheapest route alone, which corresponds to an infinite elasticity of route choice, whereas Allen and Arkolakis (2022) allow a finite one. We use the limiting case because 53% of transshipped origin-product cells use a single hub, and in the rest the main hub carries a median 73% of the value.

[8] We use the 6-digit trade elasticities of Fontagné et al. (2022).

hub, which suggests that broad deterrence, such as the legal risk that makes EU firms wary of any sale that might reach Russia, matters more than the EU's targeted measures against transshipment, which barely changed the bans' effect. Losses in the EU are far smaller, with the median member losing 0.036% of real income. In our main specification, hubs earn no rents from transshipment. If each hub instead charged as much as it could without losing the trade to a competing route, hubs would earn at most USD 2.00 billion.

Transshipment also changes which countries add most to the coalition and which goods are most effective to ban. Blocking every combination of product, origin, and hub that Russia currently uses would eliminate only 41% of its transshipment gain, because Russia switches to combinations it does not yet use.[9] A country that joins the coalition removes these as well and also restricts its own exports to Russia. For Türkiye and the UAE, most of the effect of joining comes from ending their role as hubs, for China from restricting its own exports. If the five largest hubs joined, Russia's real-income loss would rise to 2.04%, above the 1.66% that the current bans would cause without transshipment. When the EU extends its list of banned products, a list chosen without accounting for transshipment raises Russia's loss by 16% less than one that accounts for it and covers the same value of EU exports, because it bans products that Russia can keep buying through hubs.

We contribute to three strands of the literature.[10] First, we add transshipment, alongside trade diversion, to a trade model of discriminatory trade barriers and discipline it with micro data on how banned goods reach the target. Existing general-equilibrium models of the sanctions on Russia, and of trade policy more generally, account for trade diversion but not for transshipment (e.g., Chowdhry et al. 2024; Fajgelbaum et al. 2020; Fan et al. 2026; Mayer et al. 2026).[11] Because the bans are set by product, we quantify the model for each 6-digit product and, unlike earlier product-level models (French 2016; Torun 2025), let trade costs and elasticities vary by product, using only readily available data. Closest to us, Egorov et al. (2025*a*) also use Russian customs records and provide reduced-form evidence that the export bans hurt Russian firms despite transshipment, with the damage spreading through Russia's domestic production network, as in the 2014 war in eastern Ukraine (Korovkin et al. 2025).[12] We instead study how banned goods still reach Russia, through which hubs and how cheaply, and quantify in general equilibrium how much transshipment reduces the cost of the export bans to Russia.

Second, our evidence on how banned goods reach the target adds to work on the circumvention of trade policy. Most of this work infers transshipment, either from

[9] Crackdowns on drug trafficking similarly divert traffic to routes not used before (Dell 2015).

[10] For reviews of the broader literature on sanctions, see Felbermayr et al. (2025); Mohr and Trebesch (2025); Morgan et al. (2023).

[11] An exception is Funke and Wende (2025). In their three-country model, banned goods can reach Russia through the rest of the world at a cost set by assumption.

[12] For evidence on other embargoes, blockades, and security-motivated trade restrictions, see Amodio et al. (2021), Etkes and Zimring (2015), Irwin (2005), and Juhász (2018).

aggregate trade flows around tariffs (e.g., Fisman et al. 2008; Freund 2025; Liu and Shi 2019; Rotunno et al. 2013; Stoyanov 2012) and sanctions (e.g., Chupilkin et al. 2025*a*, 2026*c*; Fisman et al. 2025; Scheckenhofer et al. 2025; Tyazhelnikov and Romalis 2024) or from transaction-level data of individual hubs (Iyoha et al. 2025; Li et al. 2024).[13]Under tariffs and other barriers that the importer imposes, inference is unavoidable, because transshipment is only profitable if the good's origin is misdeclared. Under an export ban, the target has no reason to hide where a good was made, so its customs records reveal transshipment directly, provided one knows which products are fully banned, information that existing studies of these sanctions do not have.[14] Like us, Chupilkin et al. (2024) use Russian customs declarations, but they identify Western goods by their trademarks (see also Bilousova et al. 2024). Because many Western-branded goods are made outside the countries that ban them, their measure combines transshipment with trade diversion; we separate the two by following goods produced in the countries that ban them.[15]

Third, our counterfactuals speak to a central question in geoeconomics, namely how governments can use trade restrictions to put pressure on other countries.[16] Theories of geoeconomic power show that this pressure comes from goods the target cannot easily obtain from alternative suppliers (Becko 2024; Becko and O'Connor 2025; Clayton et al. 2026; Hirschman 1945; Liu and Yang 2025), and Hausmann et al. (2024) rank products to ban on this basis; once the target can buy banned goods through hubs, a different set of products imposes the largest loss. In existing work, third countries matter as alternative suppliers. Broader coalitions leave the target fewer of them (Chowdhry et al. 2024; Fan et al. 2026), and third countries gain from the trade they attract (Corsetti et al. 2025; Fajgelbaum et al. 2024). We show that third countries also matter as hubs, so that bringing one into the coalition ends its role as a route to the target as well.[17]

The paper proceeds as follows. Section 2 introduces the export-ban and customs data and explains how we measure transshipment. Section 3 estimates how much the bans raised trade costs and documents how transshipment adapted across routes, sellers, and types of intermediaries. Section 4 develops the quantitative model and calibrates it to

[13] Other work studies the misreporting of goods and prices to evade taxes and tariffs (Che et al. 2025; Fisman and Wei 2004; Javorcik and Narciso 2008; Laffitte and Toubal 2022) and the evasion of the oil sanctions (Babina et al. 2026; Cardoso et al. 2026; Fernández-Villaverde et al. 2025).

[14] Existing sanctions data record either the type of sanction by country pair (Felbermayr et al. 2020; Yalcin et al. 2025) or, for the sanctions on Russia, whether each product is sanctioned, based on the Global Trade Alert (Global Trade Alert 2026; Hausmann et al. 2024), the legal texts (e.g., Chupilkin et al. 2025*a*; Flach et al. 2024), or the customs-data provider Alta-Soft (Egorov et al. 2025*a*,*b*).

[15] Firms often cut trade with sanctioned countries by more than the law requires (Chupilkin et al. 2026*a*,*b*; Crozet et al. 2021; de Lucio et al. 2026; Li et al. 2024), and penalties deter violations (Berkowitz et al. 2025).

[16] For theoretical work on the design of sanctions and export controls, see Ahn and Ludema (2020); Alekseev and Lin (2026); Becko (2024); Eaton and Engers (1992); Itskhoki and Ribakova (2024); Kaempfer and Lowenberg (1988).

[17] On how trade shapes the alignment of third countries more generally, see Becko et al. (2025); Broner et al. (2025); Clayton et al. (2026); Kleinman et al. (2024).

these estimates and to the observed hub shares. Section 5 quantifies the effects of the export bans with and without transshipment, and Section 6 compares alternative ways of strengthening the bans. Section 7 concludes.

2 Data and Measurement

To measure transshipment, we combine two sources. First, we construct a novel product-level database of the EU export bans, recording which products are banned and since when. Second, we use Russian customs declarations, which show for each import where the good was made and part of the route it took to Russia.

2.1 The EU Export Bans

Since Russia's full-scale invasion of Ukraine in February 2022, the EU has prohibited its firms from exporting a large and growing set of products to Russia. Successive sanctions packages expanded the list of banned products, and by the end of 2024 the bans covered, fully or in part, product categories that accounted for 79% of Russia's 2019 imports from the EU (see Table .1 for details).[18] The bans are binding legal prohibitions: EU firms may not sell, supply, or export listed products to Russia, whether directly or indirectly via third countries, and may not knowingly take part in activities that circumvent the restrictions. Member states enforce the bans by investigating violations and imposing penalties, which can be criminal.[19]

Many EU export bans are defined at a more disaggregated level than the tariff line, the fine-grained product classification in which trade is recorded. For the EU, tariff lines are eight-digit Combined Nomenclature codes, or CN8, and bans are either code-based, covering all variants of a CN8 product, or text-based, covering only variants that meet a certain technical description. The February 2022 ban on aircraft exports is code-based and covers all of chapter 88, so every CN8 product within it is banned. Text-based bans instead define banned variants by technical characteristics that the CN8 classification does not record. For example, multi-component integrated circuits (CN8 8542 31 11) are banned only if their clock frequency exceeds 25 MHz, while circuits with lower clock

[18] Regulation 833/2014 formulates the measures as outright prohibitions, hence export bans. The US, by contrast, implements its Russia sanctions as export controls, which require a license for listed items and review applications under a policy of denial.

[19] See Article 12 of Regulation 833/2014. Directive (EU) 2024/1226, which member states had to transpose into national law by May 2025, requires them to criminalize intentional violations and circumvention of EU sanctions. Since February 2022, authorities in 32 European countries, including the United Kingdom, Switzerland, and Norway, have opened more than 12,500 investigations into violations of sanctions against Russia and other countries such as Belarus and Iran, and fines imposed since 2017 total nearly EUR 615 million (Handley 2026).

frequencies can still be legally exported from the EU to Russia.[20] We work at the HS6 level, the finest level at which product codes are internationally comparable and hence the level at which we can combine the EU export bans with the Russian customs data. An HS6 product is therefore only partly covered if bans apply to some of its CN8 codes but not to others.

Identifying partial coverage is central to measuring transshipment, because EU-origin imports of partially banned products can reach Russia legally and would otherwise be wrongly counted as transshipment. Our empirical analysis of how much is transshipped, through which routes, and by whom therefore focuses on fully banned products. Partial bans still covered more than a thousand products at the end of 2024, however, so the model that quantifies the effects of transshipment incorporates both groups, with separate trade cost increases for full and partial bans.

We implement the distinction between fully and partially banned products by combining the EU's Integrated Tariff (TARIC), which records which CN8 codes are restricted and since when, with a manual review of the sanctions annexes, which reveals whether a restriction covers the entire code.[21] From TARIC, we retrieve all export restrictions on Russia under Regulation 833/2014 at a daily frequency for 2022–2024. When a restriction is defined at a more aggregated level, such as an HS chapter, all CN8 codes within it inherit the restriction. TARIC does not show, however, whether a restriction covers the entire CN8 code or only some of its variants. To determine this, we use the fact that TARIC links each restriction to the provision of the regulation it implements, and thereby to the annex listing the banned goods, and check by hand how each code is listed in that annex. A restriction is text-based if the annex defines the banned goods by technical description, as for dual-use and advanced technology items, or lists the code with exceptions or value thresholds. A CN8 code is fully banned once at least one code-based restriction covers it. An HS6 product is fully banned if all of its CN8 codes are fully banned, and partially banned if at least one CN8 code is restricted but the product is not fully banned.[22]

[20] See Annex VII, item X.A.I.001.a, of Regulation 833/2014. Text-based bans restrict the variants most relevant for military use while leaving variants with mainly civilian uses tradable, in line with the targeting logic of so-called smart sanctions, which aim to restrict specific actors, sectors, or goods while limiting harm to the wider population (Morgan et al. 2023).

[21] TARIC records all EU measures governing the import and export of goods, including tariffs, documentation requirements, and import and export restrictions. It is updated daily and covers all CN8 codes. https://taxation-customs.ec.europa.eu/online-services/online-services-and-databases-customs/eu-customs-tariff-taric_en

[22] The bans are defined in the 2022 version of the nomenclature, while we express all products in the 2017 revision of the HS using standard UN concordance tables (https://unstats.un.org/unsd/classifications/Econ). An HS2017 product is classified as fully banned only if all of its corresponding HS2022 codes are fully banned, which avoids mechanically overstating the scope of the bans. At the monthly frequency, a product is coded as banned only if the restriction is in force for at least 15 days of the month.

TARIC also provides product-specific entry-into-force dates, which often differ from the publication dates of the regulations that are commonly used in the literature (e.g., Crozet and Hinz 2020; Flach et al. 2024). For example, a regulation published on February 25 may ban the export of oil-refining technology, yet continue to allow exports under contracts concluded before that date until May 27. Such phased implementation and exemptions are difficult to capture from the legal texts alone, whereas TARIC records them for each product.

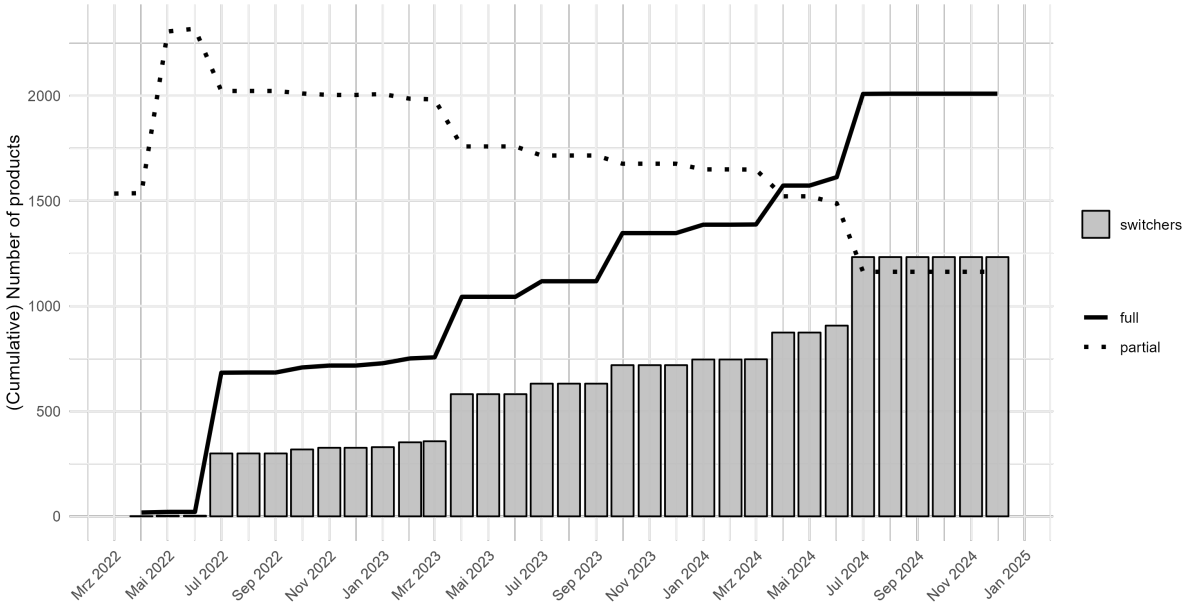

Figure 1. EU Export Bans Over Time

Note: The figure shows the cumulative number of HS6 products covered by EU export bans over time. The solid line denotes fully banned products, the dotted line partially banned products (accounting for transitions from partial to full coverage), and the gray bars indicate the number of products that switch from partial to full bans.

When the first bans took effect in March 2022, all banned products were only partially banned, but the EU converted many partial bans into full bans over time: by the end of 2024, fully banned HS6 products outnumbered partially banned ones. Figure 1 plots both counts over time. By July 2022, 51% of all HS6 products were subject to EU export bans, but only 688 of them fully, compared with 2,023 partially. By the end of 2024, 2,010 products were fully banned, while 1,163 remained partially banned. Most conversions occurred in one of two ways. First, CN8 codes initially restricted only by technical description, typically as dual-use or advanced technology items, were later listed by code in another annex, so that all of their variants became banned. Second, the EU extended a ban to the remaining CN8 codes within an HS6 product.[23] In both cases, the

[23] Conversions from text-based to code-based listings are concentrated in dual-use and high-tech goods, such as Optics and Arms & Ammunition, while extensions to the remaining CN8 codes are concentrated in Machinery & Electrical Equipment and in Plastics. See Figure .1 in the Appendix.

affected CN8 codes receive an additional code-based provision in TARIC, so our daily classification records each conversion on the day it takes effect.

2.2 EU Export Statistics

Official EU export statistics confirm that products we classify as fully banned stopped flowing directly to Russia altogether once the bans took effect. We use Eurostat's Comext database, which reports monthly exports of each EU member state by destination and CN8 product, valued in euros. Because Comext is compiled from the export declarations that EU firms file at the border, it records what the EU exports directly to Russia and to third countries. Figure 2 plots monthly EU exports to Russia of products fully banned by July 2022 and of products that remained partially banned through December 2024. Exports of fully banned products fall to zero in the month the full ban takes effect and stay there. Exports of partially banned products decline but do not collapse, consistent with many of their variants remaining legal to export.

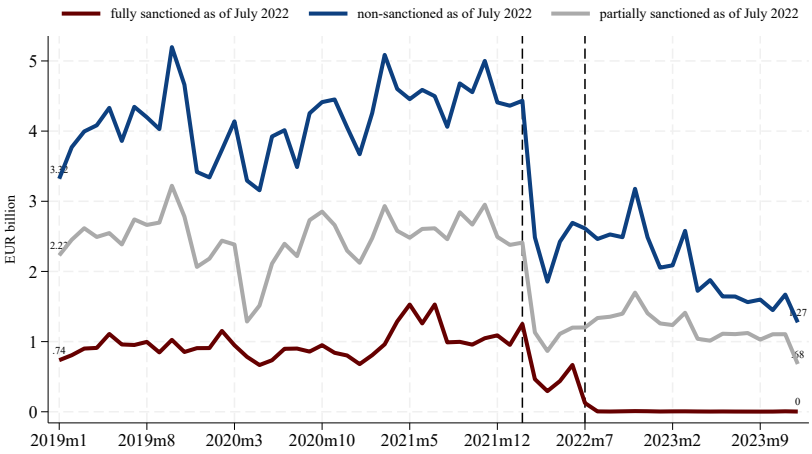

Figure 2. Direct EU Exports to Russia of Fully and Partially Banned Products
Note: The figure shows direct monthly EU exports to Russia in billion euros for products fully banned by July 2022 and products partially banned through December 2024. *Source:* Eurostat, Comext.

2.3 Russian Customs Data

Our data cover the universe of Russian import transactions from countries outside the Eurasian Economic Union (EAEU) in 2019 and 2022–2024, with detailed information on buyers, senders, products, and the start and end points of each shipment's route to

Russia.[24] Each customs declaration lists one or more transactions.[25] For each transaction, we observe the Russian buyer (name, tax ID, and address), the sender (name and address), a ten-digit product code, a detailed product description, the value in US dollars, the weight in kilograms, and three countries: the country of origin, the trading country, and the dispatch country. The country of origin is where the good was produced,[26] the trading country is the country of the seller, and the dispatch country is where carriage to the Russian buyer began, as stated in the transport document; earlier legs and transit countries are not recorded.

Two further variables describe how the goods reached Russia: the sender and the clearance office. The sender reported in the declaration is the consignor named in the transport document under which the final carriage to Russia began. The sender therefore need not be the seller: it can be the seller, the Russian buyer, a forwarder acting for either, or an intermediary that bought the goods and shipped them on to Russia.[27] The sender differs from the carrier, the firm that physically moves the goods (e.g., DHL or UPS), which the declaration does not name. The clearance office is the Russian customs office where the goods were cleared and marks the end point of the route we observe.

A single import transaction can involve several countries, each recorded in a different field, as the hypothetical transaction in Table 1 illustrates for a product not subject to the bans. A German producer sells a good to an Austrian distributor, which stores it in Poznań, Poland. A Russian buyer located in Moscow buys the good and hires a Lithuanian forwarder, which is named as consignor in the transport document and has a Polish trucking firm carry the good through Belarus to Moscow. The declaration reports Germany as the country of origin, Austria as the trading country, the Lithuanian forwarder as sender, Poland as the dispatch country, and a Moscow customs office as the clearance office, while neither the carrier's name nor the route through Belarus appears in our data. In most transactions, however, several of these fields coincide, for example, when a manufacturer sells and ships its good directly, so that the country of origin, the trading

[24] The data are not publicly available. They were obtained from the commercial provider *World Marketing* (https://worldmarketing.info/), but comparable data are available from many other providers, including *Datamyne*, *Export Genius*, and *Import Genius*. Transaction-level Russian trade records of this kind are also used by Babina et al. (2026); Chupilkin et al. (2025*a*); Egorov et al. (2025*a*); Jiao and Wei (2025). Appendix C discusses their reliability.

[25] In customs terminology, a transaction corresponds to a goods item of the declaration.

[26] Under EAEU rules, the country of origin is the country in which a good was wholly produced or last sufficiently processed. Transit, storage, or repackaging in a third country does not change a good's origin. See the non-preferential rules of origin approved by Decision No. 49 of the Council of the Eurasian Economic Commission of 13 July 2018, as amended.

[27] See box 2 in the instructions for completing the goods declaration, Decision No. 257 of the Customs Union Commission of 20 May 2010, as amended. The declaration also records the delivery terms (Incoterms). Under E- and F-terms such as EXW or FCA, the buyer or its forwarder books the main carriage; under C- and D-terms such as CPT or DAP, the seller or its forwarder does. The firm that books the carriage is not always the one named as consignor, however: under F-terms, the seller often appears as shipper on the bill of lading.

country, and the dispatch country are the same. In 2019, 83% of EU-origin import value came from such transactions.

Table 1. Parties and Route of a Hypothetical Transaction in the Customs Data

Panel A: Parties to the Transaction

Party	Example	Recorded as (box)	Definition
producer	German manufacturer	origin country, DE (16)	country where the good was produced
seller	Austrian distributor	trading country, AT (11)	country of the firm that sold the goods to the Russian buyer
sender	Lithuanian forwarder, hired by the buyer (FCA)	sender name and address (2)	party to the transport contract with the carrier
carrier	Polish trucking firm	—	not recorded
buyer	Russian buyer	consignee tax ID and name (8)	Russian firm the goods are delivered to

Panel B: Physical Route of the Goods

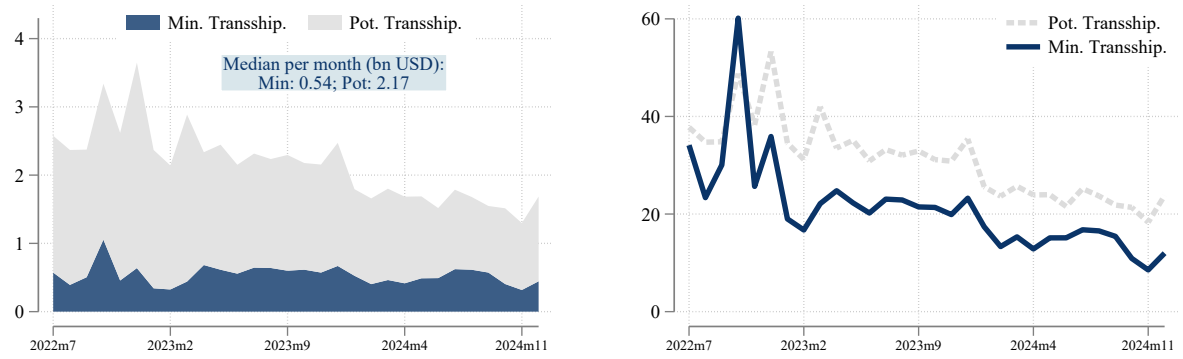

Leg	Example	Recorded as (box)	Definition
producer	German manufacturer	origin country, DE (16)	country where the good was produced
first trip	to the distributor's warehouse in Poznań	—	carriage to someone other than the Russian buyer
dispatch	Poznań	dispatch country, PL (15)	first country where the goods were accepted for carriage to the Russian buyer
transit	Belarus	—	countries crossed after dispatch
clearance	customs office, Moscow	office code (30)	customs office for the region of the buyer's warehouse

Note: Stylized transaction of a product not subject to the bans. Box numbers refer to the EAEU goods declaration (Decision No. 257 of the Customs Union Commission of 20 May 2010). A dash means the declaration does not record the party or the leg of the physical route.

2.4 Measuring Transshipment

We define transshipment as Russian imports of banned EU-origin goods. Measuring it requires combining the country-of-origin information in the Russian customs records with information on whether the EU export bans cover the respective product fully or only partially. For products fully banned at the time of import, every EU-origin import counts as transshipment, because the ban rules out legal direct exports; consistent with this, EU export statistics record none (Figure 2). Banned variants of partially banned products are likely transshipped as well, but our data are too aggregated to separate them from permitted variants, which EU firms may still export to Russia directly. EU-origin imports of fully banned products therefore give a lower bound on transshipment, and adding EU-origin imports of partially banned products gives an upper bound. Without the distinction between full and partial bans, legal direct exports of permitted variants

would be counted as transshipment, overstating its magnitude.[28] The resulting flows are substantial, amounting to between USD 0.5 and 2 billion per month, or about 20% of pre-war imports of the same products (Figure 3).

(A) Volume (USD bn per month) (B) Share of Pre-War Imports

Figure 3. Transshipment of Banned EU-Origin Goods to Russia

Notes: The figure shows monthly Russian imports of EU-origin goods under an EU export ban, from June 2022 to December 2024. The lower bound includes only HS6 products fully banned in that month; the upper bound adds partially banned HS6 products, in which only some tariff lines are banned. Panel B expresses the values relative to average monthly 2019 imports of the products banned in that month.

EU firms largely stopped selling fully banned products to Russian buyers, at least on paper. Transshipment has a contractual and a physical dimension, which the customs declarations record in the trading and the dispatch country, respectively. The trading country captures the contractual dimension, namely who officially sells the goods to the Russian buyer. Because any contract between an EU seller and a Russian buyer would violate the ban, the seller of a fully banned EU-origin product should be located outside the EU, whatever physical route the goods take. In line with the bans, the EU's share as trading country fell from 77% of the value of these imports in January 2019 to 15% in December 2024 (Figure 4, Panel A). For never-banned products, the share remained high, at 75% in 2019 and 82% in 2024 (Panel B).

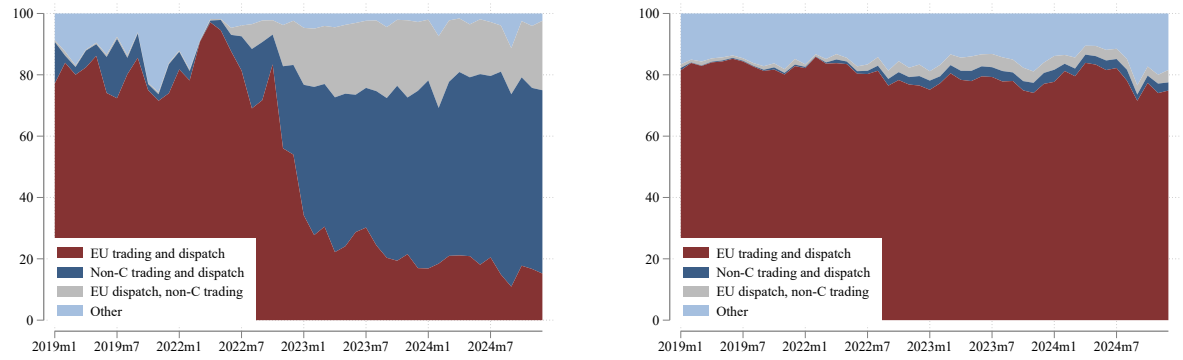

Physically, banned goods reach Russia in one of two ways, re-exported from a third country or diverted en route after leaving the EU. For a re-export, a firm in a third country buys the goods and ships them on to the Russian buyer, so that country is both the trading and the dispatch country, and the contractual and physical routes coincide. Goods diverted en route instead leave the EU declared for export to a third country, such as Kazakhstan, and the sender has the carrier redirect them to Russia along the way.[29] They enter Russia either through a non-EU transit country, most often Belarus, where

[28] Studies that classify products solely as sanctioned or not, such as Egorov et al. (2025*a*), correspond to our upper bound.

[29] The sender recorded in the Russian declaration is often an EU firm, because the shipment starts in the EU and its transport documents name the original shipper unless they are reissued en route. An EU sender therefore need not have violated the ban, since the goods may have been sold to a buyer in a third country who then arranged the diversion.

the redirection takes place, or directly, usually from the Baltic states, and are cleared at a Russian customs office.[30]

The dispatch country tells the two modes apart, and in December 2024, re-exports accounted for 60% of the value of EU-origin imports covered by the full bans and diversions en route for 39% (Figure 4). Because a diverted shipment began in the EU, the declaration records an EU member as the dispatch country, regardless of where the seller, recorded as the trading country, is located. Were the good in Table 1 fully banned, a re-export via a Turkish trading firm would record Türkiye as both dispatch and trading country, whereas a diversion en route would record an EU member as the dispatch country and, depending on the paperwork, a third country or an EU member as the trading country. For never-banned products, by contrast, re-exports through non-coalition countries remain negligible, at 2% of import value.

(A) Fully Banned by July 2022 (B) Never Banned

Figure 4. Trading and Dispatch Countries of EU-Origin Imports (in %)

Notes: Monthly (2019, 2022–24) shares of each trading–dispatch country combination in the value (USD) of Russian imports of EU-origin products, by ban status. For banned products, non-coalition trading and dispatch countries indicate re-exports, and an EU dispatch country indicates diversion en route.

Diversions en route also explain why the EU share as trading country declined only gradually and never reached zero. Russian customs record as trading country the country in which the Russian importer's counterparty is registered or, absent a contract, the country indicated in the commercial documents, such as the invoice.[31] Shipments diverted en route can keep the EU seller as counterparty, in violation of the ban, or arrive with its invoice, so customs record an EU member as trading country, while EU export statistics show the third country as destination. In the first months after the bans, many diversions ran on such EU paperwork. Over time, intermediaries in third countries increasingly invoiced the goods themselves, so the recorded trading country moved outside the EU even for goods still dispatched from the EU.

[30] Goods cleared in another EAEU member, such as Belarus, and then moved on to Russia do not appear in our data, so our measure understates transshipment.

[31] See box 11 in the instructions for completing the goods declaration, Decision No. 257 of the Customs Union Commission of 20 May 2010, as amended.

Whatever the mode, nearly all transshipped goods pass physically through a third country before entering Russia, and we call that country the transshipment hub. In a re-export, the hub is simply the country where a firm buys the goods and resells them to the Russian buyer. Goods diverted en route also tend to pass through a third-country hub, because they are easier to redirect once they are beyond the reach of EU enforcement, for example when goods declared in transit to Kazakhstan cross Belarus, which has no customs border with Russia, and end up in Moscow instead. In both cases, goods flow through the countries that make indirect exports from the EU to Russia cheapest. Such countries typically border Russia or the EU, share a customs union with either, or lie on established freight corridors. Our model in Section 4 captures these differences through hub-specific wedges, which determine how costly it is to redirect goods through a country.

For imports diverted en route, the customs declarations do not show where the goods were redirected, so we infer the hub from their most likely route to Russia. The declarations record the EU country from which the goods were dispatched to Russia and the Russian customs office at which they were cleared.[32] We compute the fastest connection between these two locations, which may combine road, ferry, and container-ship legs, and take the first non-EU country along it as the hub. If the route crosses no third country, the redirection must take place within the EU, and we take the last EU country before the Russian border as the hub. In 2024, 58% of the value of diverted imports passed through Belarus and 6% through Türkiye, while 17% entered Russia directly from Latvia. Taking both modes together, 90% of the value of all transshipped imports passed through a hub outside the EU.

2.5 Data Quality of the Customs Data

A natural concern is whether the Russian customs records remain reliable after the invasion. At least three pieces of evidence make us confident that they do. First, the records closely track the exports reported by Russia's non-sanctioning trading partners, both in aggregate and by HS2 sector and partner country (Figure C.1).[33] The only exception is arms and ammunition, which we therefore exclude from all analyses.

Second, criminal investigations by Western authorities that started from such records corroborate that the records capture even illegal transactions. For example, Dutch journalists used Russian customs records in December 2023 to show that a Dutch firm

[32] Clearance offices are available only for 2023–2024 and are missing for the first quarter of 2024. Because direct flights between the EU and Russia ceased in 2022, we assign hubs to EU-dispatched imports cleared at an airport in proportion to their shares among non-EU-dispatched imports cleared at the same airport.

[33] Other studies using the Russian customs data compare total Russian imports with official and mirror statistics and find a close match (Babina et al. 2026; Chupilkin et al. 2025*b*; Egorov et al. 2025*a*). We extend this comparison to sectors and partner countries.

had shipped sanctioned goods to Russia, and in January 2024 Dutch authorities arrested three people associated with the firm on suspicion of sanctions violations.[34] Similarly, the Munich public prosecutor's office opened an investigation into a German machine tool manufacturer in February 2025, shortly after a television report based on Russian customs records had traced the firm's machines to Russia via third countries, and later charged three of its employees.[35]

Third, the only documented case in which Russian authorities altered the customs records occurred at the end of our sample period, and they did so by ceasing to record sensitive imports rather than by falsifying their origin or product codes. According to investigative reporting, Russian customs stopped recording imports in about 180 product codes covering sanctioned electronics and industrial equipment from the end of 2024 onward (The Insider 2025). The imports never reappeared under other codes or from other countries of origin, and the importing firms remained active, which rules out that they simply stopped importing. Although none of these checks can rule out manipulation entirely, together they indicate that the Russian customs records provide a reliable basis for our analysis.

3 Reduced Form Evidence of Transshipment

Next, we document three facts about transshipment of banned EU goods to Russia: how much more costly it made these goods, which firms carried it out, and which routes it took.

3.1 Estimating the Actual Trade-Cost Increase

Gravity lets us infer how much the bans raised trade costs from how much Russian imports of banned EU goods fell. A broad class of trade models delivers the same gravity structure (Arkolakis et al. 2012; Head and Mayer 2014), which is also consistent with our framework

[34] The journalists obtained the customs records from the commercial data provider ImportGenius (https://nos.nl/nieuwsuur/collectie/13964/artikel/2501582-verantwoording-onderzoek-nieuwsuur-handel-naar-rusland), which distributes the same underlying customs records as our data; the entries we compared are identical. On the arrests, see the press release of the Dutch Fiscal Information and Investigation Service (https://www.fiod.nl/drie-aanhoudingen-in-onderzoek-naar-omzeiling-sanctiewetgeving/) and the report linking the investigation to the journalists' findings (https://nltimes.nl/node/70750).

[35] The report, broadcast by Arte on January 29, 2025, draws on records from the commercial data provider ExportGenius (https://www.zdf.de/video/magazine/collection-index-page-artede-collection-artede-rc-024364-1746/page-video-artede-mit-offenen-daten---enthuellungen-ueber-einen-verbotenen-handel-100), which likewise distributes the same underlying customs records as our data. On the investigation, see the prosecutor's statement as reported in https://www.produktion.de/wirtschaft/sanktionsverstoss-durchsuchungen-bei-werkzeugmaschinenhersteller-284.html and https://www.handelsblatt.com/unternehmen/mittelstand/mittelstand-ermittlungen-gegen-maschinenbauer-wegen-russland-sanktionen/100145150.html.

(see Section 4). In all of them, Russian imports of product k from origin e in month t take the following form in logs:

$$\log X_{et}^k = \underbrace{\log A_{et}^k}_{\text{exporter-specific}} + \underbrace{\log B_t^k}_{\text{importer-specific}} - \underbrace{\theta^k \log \tau_{et}^k}_{\text{bilateral trade cost}} . \tag{1}$$

The exporter-specific term A_{et}^k summarizes the supply side, namely how competitive the origin e is in the product k, regardless of destination. On the demand side, the importer-specific term B_t^k measures how much Russia buys of product k in a given month and how many suppliers compete for those purchases. It rises, for example, when the war economy increases Russian demand for certain products.[36] The bilateral term τ_{et}^k is the trade cost for Russia of sourcing product k from origin e, to which imports respond with the trade elasticity θ^k. The bans enter through this term as $\log \tau_{et}^k = \delta_t^F S_F^k \, EU_e + \log \tau_e^k + \log \tau_{et}$, where S_F^k indicates fully banned products, EU_e indicates the 27 EU member states, and δ_t^F is the log increase in trade costs caused by the full bans in month t. The remaining terms capture time-invariant and origin-wide trade costs. Substituting this expression into equation (1) and replacing the exporter- and importer-specific terms and the remaining trade-cost terms with fixed effects yields our estimating equation, whose coefficient on the ban indicator measures the average of $-\theta^k \delta_t^F$ across fully banned products.

We estimate the trade-cost increase with a triple-difference-in-differences (triple DiD) event study at the HS6–origin–month level for 2019 and 2022–2024.[37] Identification comes from the change in Russian imports of banned products from the 27 EU member states, relative to the same products from non-coalition origins and to never-sanctioned products, estimated separately for each month. Besides never-sanctioned products, the sample includes only products fully banned by July 2022, so that each product's treatment status stays fixed after the bans take effect. The estimating equation is

$$X_{et}^k = \exp\Big[\sum_{m \neq m_0} \beta_m^F \cdot S_F^k \cdot EU_e \, \mathbf{1}\{t = m\} + \mu_e^k + \mu_{et} + \mu_t^k \Big] + \epsilon_{et}^k, \tag{2}$$

where X_{et}^k denotes Russia's imports of product k from origin e in month t, the ban indicator is defined as above, and m_0 is the first quarter of 2019 (January–March), the reference period. We estimate equation (2) by Poisson pseudo-maximum likelihood (Santos Silva and Tenreyro 2006). Unlike a log-linear regression, PPML is consistent under heteroskedasticity and keeps zero flows, which matter here because the bans aim to push flows to zero. Standard errors are two-way clustered by product and origin country.

[36] In the Eaton–Kortum model, for example, $A_{et}^k = T_e^k \, w_{et}^{-\theta^k}$, where T_e^k is technology and w_{et} the wage, and $B_t^k = X_t^k \, (P_t^k)^{\theta^k}$ up to a constant, where X_t^k is Russian expenditure on product k and P_t^k its price index.

[37] The sample excludes coalition countries outside the EU, for which we cannot distinguish between partially and fully banned products.

The fixed effects absorb the supply and demand terms of the gravity equation and the trade costs unrelated to the bans, so the treatment coefficients capture only the ban-induced change in trade costs. Product–origin fixed effects μ_e^k absorb exporters' persistent productivity measures and time-invariant trade cost factors, τ_e^k, such as distance. Origin–month fixed effects μ_{et} absorb changes in each origin's competitiveness, such as wages, and origin-wide trade cost shocks τ_{et} that hit all of an origin's products alike. Other sanctions and war-related shocks fall into this category: financial sanctions, the exclusion of Russian banks from SWIFT, each origin's exchange rate against the ruble, and the reputational risk of trading with Russia affect all exports of an EU member state, not only banned products. Product–month fixed effects μ_t^k absorb the demand side, that is, Russian demand for product k and the competition among its suppliers. They also absorb Russia-wide shocks such as swings in the ruble or in oil prices, which shift demand for a product regardless of its origin.[38]

The full export bans reduced Russian imports of fully banned EU-origin products by 85%, and the effect persisted through the end of 2024 (Figure 5). The decline is measured relative to imports of the same products from non-coalition origins and relative to imports of never-sanctioned products. We find no evidence of differential pre-trends, and the coefficients remain insignificant in the first months of the war, when most of the bans were not yet in force.

The declines imply that importing banned EU goods became considerably more costly, but far from prohibitively so. We recover the trade cost increase for each product by rescaling the static estimate with its own trade elasticity, $\exp(-\hat{\beta}/\theta^k) - 1$, using the product-specific elasticities from Fontagné et al. (2022). For the median fully banned flow, sourcing the product after the ban is 69% more costly than importing it directly before the war. A perfectly enforced ban would raise trade costs to infinity, while the finite increase instead reflects the cost of reaching Russia through transshipment.

3.2 Adjustment Along Routes and Sellers

The stable aggregate effect of full export bans masks a shift in how the remaining imports reach Russia. From late 2022 to autumn 2024, the effect in Figure 5 stays near −85 percent, although the coalition stepped up enforcement against circumvention throughout the period, from bans on transit through Russia to contractual re-export clauses and

[38] With Russia as the only importer, the product–month fixed effects are importer–product–month fixed effects. Origin–product–month fixed effects would absorb the treatment, so we assume that supply shocks in EU member states, such as wage changes, did not differ systematically between banned and other products.

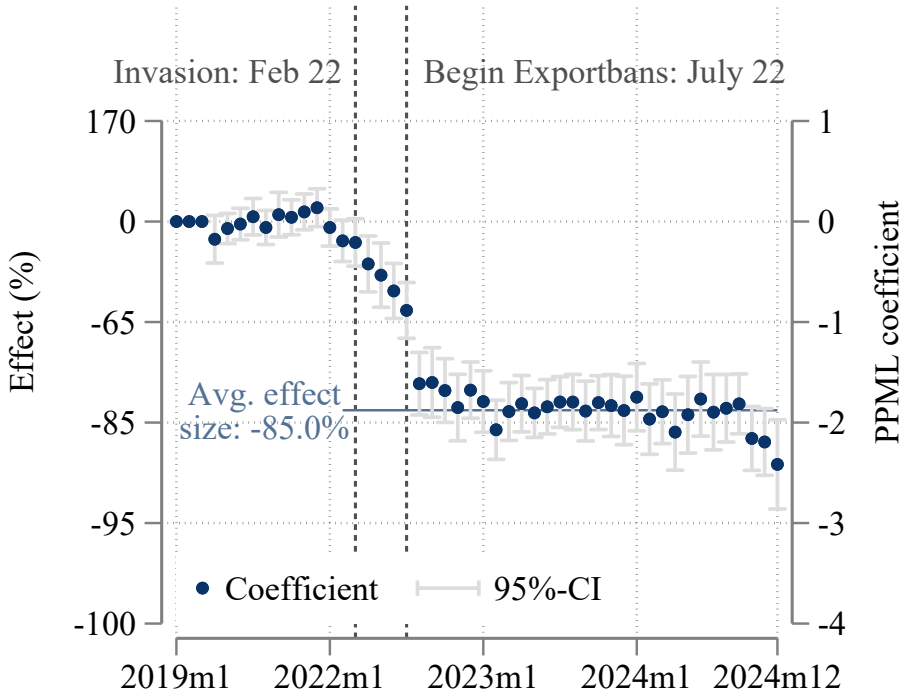

Figure 5. Event Study: Full Export Bans and Russian Imports

Notes: The figure plots monthly PPML coefficients $\hat{\beta}_m^F$ of equation (2) for Russian imports of products fully banned by July 2022, with never-sanctioned products as controls and HS 88 excluded. Coefficients are relative to the first quarter of 2019 (January–March; right axis); the left axis shows implied trade-flow changes, $(e^{\hat{\beta}_m^F} - 1) \times 100\%$. The horizontal line marks the average post-ban effect. Bars show 95% confidence intervals clustered by product and origin; vertical lines mark the invasion (February 2022) and the export bans (July 2022).

sanctions on third-country intermediaries.[39] To see whether the type of transshipment changes, we split the treated EU-origin imports in two ways and re-estimate equation (2) for each subset, keeping imports from non-coalition origins as controls. The first split compares goods dispatched from the EU with goods dispatched by non-coalition countries. The second takes goods dispatched from the EU and compares all of them with the subset sold by an EU trading party. Since each series comes from its own regression, we compare how the series evolve, not their levels. In the second split, one series is a subset of the other, so the gap between them approximates the change in the share sold by EU trading parties.

Imports of EU-origin goods dispatched from non-coalition countries respond immediately to the ban and then stay at that high level, while those dispatched from the EU erode gradually. Panel A of Figure 6 shows that non-coalition dispatch rises by roughly 170% ($\hat{\beta}_m^F \approx 1$) as soon as the ban takes effect and remains at that level through 2024.[40] EU

[39] The EU banned the transit of a growing set of banned goods through Russia from February 2023 (Regulations (EU) 2023/427 and 2023/1214) and required exporters of the most sensitive goods to include "no re-export to Russia" clauses in contracts from March 2024 (Regulation (EU) 2023/2878).

[40] The increase starts from a low base: before the war, non-coalition countries dispatched only a small share of EU-origin imports of fully banned products (Figure 4).

dispatch instead keeps falling, from −85% in August 2022 ($\hat{\beta}_m^F = -1.9$) to −96% in September 2024 ($\hat{\beta}_m^F = -3.3$). Since the aggregate effect remains stable over the same period, non-coalition dispatch must absorb the lost value, consistent with its rising share in Figure 4; panel A is too imprecise to detect the corresponding increase directly.

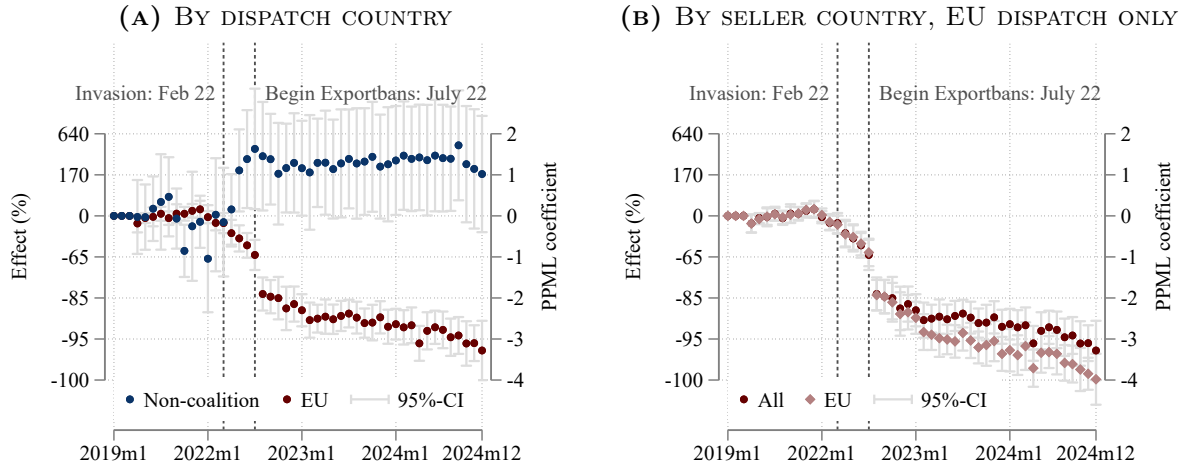

Figure 6. Event Study: Banned EU-Origin Imports by Dispatch and Seller

Notes: The figure plots monthly PPML coefficients $\hat{\beta}_m^F$ of equation (2) for Russian imports of EU-origin products fully banned by July 2022, with non-coalition origins and never-sanctioned products as controls and HS 88 excluded. Panel A compares EU-origin goods dispatched from the EU with those dispatched and sold by non-coalition countries (re-exports); panel B compares all goods dispatched from the EU with the subset also sold by an EU trading party, so a gap signals a shift to non-EU sellers on paper. Each series comes from a separate regression, so coefficients do not add up across series. Coefficients are relative to the first quarter of 2019 (January–March; right axis); the left axis shows implied trade-flow changes, $(e^{\hat{\beta}_m^F} - 1) \times 100\%$. Bars show 95% confidence intervals clustered by product and origin; vertical lines mark the invasion (February 2022) and the export bans (July 2022).

As enforcement tightens, the remaining EU sellers lengthen the transaction chain on paper only, adding a trading party in a third country while the goods are still dispatched from the EU and diverted en route.[41] Panel B of Figure 6 shows that imports dispatched and sold by EU parties move with all EU-dispatched imports until late 2022 and then fall faster, reaching −98% by the end of 2024 ($\hat{\beta}_m^F = -3.98$). Direct sales of banned goods by EU parties to Russia, the transshipment mode that leaves the clearest record of a violation, have thus nearly vanished from the Russian customs data. The gap between the two series shows, however, that the decline in EU-sold imports is not matched by a decline in EU dispatch; the goods increasingly leave the EU with a non-EU seller.

[41] The shift is specific to EU dispatch. Imports dispatched from non-coalition countries are almost always also sold by a non-coalition trading party.

3.3 The Role of Intermediaries

Banned EU-origin goods increasingly reach Russia through trading firms rather than through the firms that produce them. We identify trading firms from the sender names on the customs declarations.[42] A hand-coded dictionary of 29 terms in eight languages, matched as whole words, flags a sender as a trading firm if its name contains terms such as "trading," "import-export," or the Turkish *dış ticaret* (foreign trade).[43] Trading firms account for 13.2% of the 1.1 million distinct sender names. Because names without such a term remain unflagged, the measure is a lower bound on the role of trading firms.

The shift toward trading firms began right after the bans and grew steadily through 2024. We re-estimate equation (2) by OLS with the share of declarations filed by trading firms in each HS6–origin–month cell as the outcome, keeping only the interaction for fully banned products. The specification weights each cell by its number of declarations, and clusters standard errors by origin and product. Relative to the control groups the share of declarations for fully banned EU-origin products filed by trading firms rose by 5 percentage points in August 2022, the month after the bans took effect, and by 15 percentage points by 2024, with no pre-trends (Figure 7).

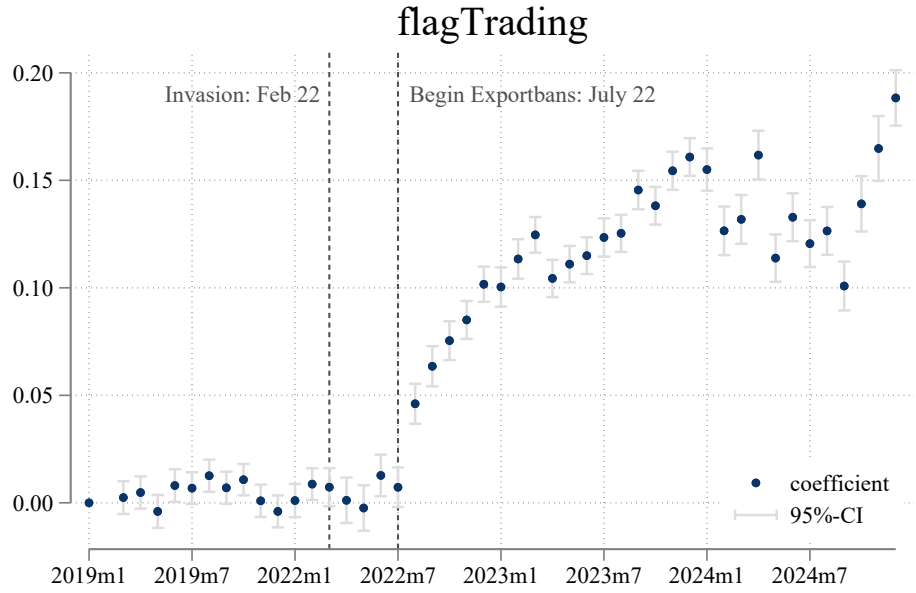

Figure 7. Trading Firms Among Senders of Fully Banned Products

Notes: The figure shows the monthly coefficients of the triple-difference event study in equation (2), estimated with the share of declarations filed by trading firms in each HS6–origin–month cell as the outcome. The coefficients compare fully banned with never-sanctioned products and EU member states with non-coalition origins, relative to January 2019, and are expressed in percentage points. The regression is linear and weighted by the number of declarations per cell. Bars show 95% confidence intervals based on standard errors clustered by origin and product. The years 2020 and 2021 are not observed.

[42] The sender is the firm named as consignor in the transport document, that is, the firm that booked the transport (Section 2.4).
[43] Appendix D lists the full dictionary.

4 A Quantitative Model of International Trade and Transshipment

To quantify how much transshipment undermines the export bans and how alternative policies would change that, we develop a general-equilibrium trade model in which banned goods reach Russia endogenously through transshipment hubs. The framework combines a multi-product Eaton and Kortum (2002) (henceforth, EK) structure, which captures substitution across source countries within narrowly defined products, with two features that matter for export bans. First, nested final demand distinguishes military-relevant goods, other critical goods, and all remaining goods, allowing substitution across these broad groups to be harder than substitution across products within a group. Second, export bans do not necessarily stop Russia from buying banned goods. Partial bans raise the cost of direct exports (without prohibiting them), and fully banned coalition-origin goods can reach Russia through third-country intermediaries, which differ in their capability in rerouting banned goods.

The model distinguishes trade diversion, Russia's substitution toward non-sanctioning producers, from transshipment, through which a banned EU product still reaches Russia through a hub. We use it to quantify the effects of the export bans on trade flows, real income, and access to military-relevant and critical goods, and to study how transshipment opportunities affect the design of export bans. The calibration in Section 4.3 builds on the estimated trade cost increases from the bans that we estimated with the triple-difference design in Section 3.1.

4.1 The Baseline Economy

The framework builds on the multi-product version of EK (see Costinot et al. 2012; French 2016). Countries trade intermediate varieties that are assembled into a finite set of non-tradable final products. Countries are indexed by $e, i \in \{1, 2, \ldots, N\}$, where e denotes the exporter and i the importer. Products are indexed by $k \in \{1, 2, \ldots, K\}$, while ω^k indexes the tradable intermediate varieties used to assemble product k.

We divide products into three mutually exclusive and exhaustive groups, $\mathcal{G} = \{M, C, O\}$, where M denotes military-relevant goods, C other critical goods, and O all remaining goods. Let $\mathcal{K}_g$ denote the set of products assigned to group g, and let $g(k)$ denote the group containing product k.

Labor is the only production input and households supply it inelastically to competitive domestic producers. We first describe final demand and then turn to production, trade, and equilibrium.

4.1.1 Demand Side: Households

Country i is populated by L_i households, each of which inelastically supplies one unit of labor to domestic producers. For tractability, we represent their aggregate final absorption through a representative household.[44] The representative household has CES preferences over the three non-tradable group composites,

$$U_i = \left[\sum_{g\in\mathcal{G}} (\alpha_i^g)^{1/\nu} (Q_i^g)^{\frac{\nu-1}{\nu}}\right]^{\frac{\nu}{\nu-1}}, \qquad \nu > 0, \tag{3}$$

where $\alpha_i^g > 0$ is a group-specific demand weight, normalized such that $\sum_g \alpha_i^g = 1$, and ν is the elasticity of substitution across the three broad groups (M, C, and O).

Each group composite is assembled from the products assigned to that group, $\mathcal{K}_g$,

$$Q_i^g = \left[\sum_{k\in\mathcal{K}_g} (q_i^k)^{\frac{\sigma_g-1}{\sigma_g}}\right]^{\frac{\sigma_g}{\sigma_g-1}}, \qquad \sigma_g > 0, \tag{4}$$

where σ_g governs substitution across products within group g. Finally, every product k is composed of a continuum of k-specific tradable varieties, with the measure of varieties normalized to one,

$$q_i^k = \left[\int_0^1 \left(q_i^k(\omega^k)\right)^{\frac{\eta^k-1}{\eta^k}} \mathrm{d}\omega^k\right]^{\frac{\eta^k}{\eta^k-1}}.$$

We assume $\eta^k > \sigma_{g(k)} \geq \nu > 0$, with the usual limiting expressions when an elasticity equals one. Thus, varieties within a specific product are closer substitutes than different products, while products within the same broad group can be closer substitutes than products of different groups. When $\sigma_g = \nu = \sigma$ for all groups, the two upper tiers reduce to a single CES aggregator over products, in which each product has the demand weight of its group.

The representative household maximizes utility subject to the budget constraint $E_i \geq \sum_{k=1}^K \int_0^1 p_i^k(\omega^k) q_i^k(\omega^k)\,\mathrm{d}\omega^k$, where E_i is aggregate income and $p_i^k(\omega^k)$ is the minimum delivered price of variety ω^k across all potential source countries, as explained in the next subsection. Let P_i^k, P_i^g, and P_i denote the product-, group-, and aggregate price indices

[44] This is only an expositional convention. Equivalently, competitive assemblers could purchase the tradable varieties, combine them first into product k and then into the three group composites M, C, and O, and sell those composites to the representative household. With constant returns and zero profits, the assemblers' unit costs are exactly the price indices derived below, so the demand and equilibrium conditions are unchanged.

in country i, respectively. Expenditure minimization yields

$$P_i^k = \left[\int_0^1 \left(p_i^k(\omega^k)\right)^{1-\eta^k} \mathrm{d}\omega^k\right]^{1/(1-\eta^k)}, \tag{5}$$

$$P_i^g = \left[\sum_{k\in\mathcal{K}_g} (P_i^k)^{1-\sigma_g}\right]^{1/(1-\sigma_g)}, \tag{6}$$

$$P_i = \left[\sum_{g\in\mathcal{G}} \alpha_i^g (P_i^g)^{1-\nu}\right]^{1/(1-\nu)}. \tag{7}$$

Let $X_i^g = P_i^g Q_i^g$ and $X_i^k = P_i^k q_i^k$ denote group- and product-level expenditure, with $X_i = \sum_{g\in\mathcal{G}} X_i^g = \sum_{k=1}^K X_i^k$. The expenditure shares are then

$$\frac{X_i^g}{X_i} = \alpha_i^g \left(\frac{P_i^g}{P_i}\right)^{1-\nu}, \tag{8}$$

$$\frac{X_i^k}{X_i^g} = \left(\frac{P_i^k}{P_i^g}\right)^{1-\sigma_g}, \qquad k \in \mathcal{K}_g. \tag{9}$$

Combining the two expressions,

$$\frac{X_i^k}{X_i} = \alpha_i^{g(k)} \left(\frac{P_i^{g(k)}}{P_i}\right)^{1-\nu} \left(\frac{P_i^k}{P_i^{g(k)}}\right)^{1-\sigma_{g(k)}}. \tag{10}$$

The upper nest governs substitution across the three broad product groups. For a given increase in a group's relative price, a lower ν causes its expenditure share to fall less (and even to rise if $\nu < 1$). The model therefore allows Russia to protect expenditure on strategically important products when they become more costly, rather than assuming that Russia substitutes between, for example, military inputs and ordinary consumer goods as easily as between products of the same group.[45]

Next, we outline how the intermediate varieties are produced and shipped.

4.1.2 Supply Side: Production of Tradable Varieties

Intermediate varieties are produced and shipped by perfectly competitive firms using labor as the only input in production.

Trade costs. Throughout the paper, we index the exporter by e and the importer by i. A subscript ei can be read as "from country e to i." Intermediate varieties can be

[45] The military-relevant composite is a model-based measure of real access to that product group. It should not be interpreted as a direct measure of military capability or as a military production function.

traded subject to standard iceberg trade costs. Firms in e need to ship $\tau_{ei}^k \geq 1$ units of a variety ω^k for one unit to arrive in i. We normalize $\tau_{ii}^k = 1$ and assume that the so-called triangle inequality holds, such that $\tau_{ei}^k \leq \tau_{eh}^k \tau_{hi}^k \; \forall (e, h, i, k)$. This no-arbitrage condition will be central in the transshipment analysis, as detailed in Section 4.2.

Production technology. Labor is perfectly mobile across products but immobile across countries, which yields a common wage across products within each country. Firms operate under perfect competition with constant returns to scale, and $\varphi_e^k(\omega^k)$ denotes the labor productivity of country e in producing variety ω^k. Hence, the cost of producing one unit of ω^k and shipping it to i is given by the marginal cost, $c_{ei}^k(\omega^k) := (w_e \tau_{ei}^k)/\varphi_e^k(\omega^k)$, where w_e is the wage rate in country e. Note that $c_{ei}^k(\omega^k)$ is also the price offered by e to i under perfect competition.

Following the literature, we assume that $\varphi_e^k(\omega^k)$ is drawn independently from a Fréchet distribution, $F_e^k(\varphi) = \exp(-T_e^k \varphi^{-\theta^k})$ for $\varphi > 0$, where T_e^k measures country e's overall level of technology in producing the varieties of product k (a higher T_e^k raises average productivity) and hence governs comparative advantage across products, and θ^k is inversely related to the dispersion of productivities and thereby governs the forces of comparative advantage across the varieties of a product.

4.1.3 Trade Flows and Equilibrium

Trade. Consumers pick the lowest-cost source of a variety across the world. This, coupled with the Fréchet distribution, yields the familiar gravity equation of trade flows (i.e., the expenditure share in country i on varieties from e and product k)[46]

$$\pi_{ei}^k := \frac{X_{ei}^k}{X_i^k} = \frac{T_e^k \left(w_e \tau_{ei}^k\right)^{-\theta^k}}{\sum_{l=1}^N T_l^k \left(w_l \tau_{li}^k\right)^{-\theta^k}}, \tag{11}$$

where X_{ei}^k is country i's expenditure on product-k varieties sourced from e, and $X_i^k := \sum_{e=1}^N X_{ei}^k$ is country i's total expenditure on product k. We refer to π_{ei}^k as the "trade share." Intuitively, trade flows are higher, the more productive e is on average (higher T_e^k), and the lower its input and trade costs (lower $w_e \tau_{ei}^k$) relative to the other countries. We refer to θ^k as the "trade elasticity," because a higher θ^k implies that trade flows are more elastic with respect to changes in trade costs (as technologies are less dispersed and technological cost differences hence less pronounced). After a product-specific normalization of technology,

[46] This follows from standard derivations (see Costinot et al. 2012; Eaton and Kortum 2002).

the denominator in equation (11) gives the product-level price index,[47]

$$P_i^k = \left[\sum_{e=1}^{N} T_e^k \left(w_e \tau_{ei}^k \right)^{-\theta^k} \right]^{-1/\theta^k}. \tag{12}$$

Note that the nested final-demand structure affects how total expenditure is allocated across and within product groups, but it does not change the sourcing problem conditional on product k. The gravity equation and the product-level EK price index therefore retain their standard form with and without upper-tier demand nests.

Baseline equilibrium. Because firms are perfectly competitive and labor is the only production input, labor-market clearing requires producer income to equal total expenditure on the country's goods,

$$w_e L_e = \sum_{i=1}^{N} \sum_{k=1}^{K} \pi_{ei}^k X_i^k. \tag{13}$$

Labor is also the only source of household income, so $X_i = w_i L_i$. Together with the nested expenditure shares, these conditions determine the baseline wage vector up to a numéraire. They also imply the standard balanced-trade condition, i.e., the value of each country's total imports equals the value of its total exports.

4.2 Export Bans and Transshipment

We introduce export bans and transshipment in three steps. First, we use the triangle inequality (TI) to recover the minimum post-sanction rerouting costs implied by the pre-war trade network. Second, we allow third-country transshipment hubs to differ in their capability in rerouting banned goods, which helps the model match the observed distribution of transshipment hubs and the estimated effect of the full bans (see Section 3.1). Third, we introduce partial bans, which raise the cost of direct exports without prohibiting them. For notational convenience, let R denote Russia from here on.

[47] Before this normalization, the exact price index is

$$P_i^k = A_k \left[\sum_{e=1}^{N} T_e^k \left(w_e \tau_{ei}^k \right)^{-\theta^k} \right]^{-1/\theta^k}, \qquad A_k := \Gamma\left(\frac{\theta^k + 1 - \eta^k}{\theta^k} \right)^{1/(1-\eta^k)}.$$

Because A_k (consisting of the Gamma function, $\Gamma(\cdot)$) is common to all origins and destinations within product k, we can define $\widetilde{T}_e^k := A_k^{-\theta^k} T_e^k$. This rescaling leaves the trade shares in equation (11) unchanged and absorbs A_k into the technology term. Relabeling $\widetilde{T}_e^k$ as T_e^k gives equation (12) with equality. We assume $\theta^k > \eta^k - 1$, which ensures that the product-level price index is finite.

4.2.1 The Triangle Inequality and Transshipment

To measure transshipment opportunities, we rely on the triangle inequality of trade costs,

$$\tau_{ei}^{k} \leq \tau_{eh}^{k} \tau_{hi}^{k} \qquad \forall (e, h, i, k), \tag{14}$$

building on recent insights from Foellmi et al. (2024). In words, the TI is a no-arbitrage condition. The trade cost assigned to supplying product k from country e to country i cannot exceed the cost of supplying the same product through an intermediary located in a third-country hub h. Otherwise, firms would use the cheaper indirect route, and the effective bilateral trade cost would become $\tau_{eh}^{k} \tau_{hi}^{k}$.[48]

The TI becomes particularly important after a shock. Starting from the TI-consistent baseline matrix τ, let $\tilde{\tau}'$ denote the trade-cost matrix immediately after the direct policy shock, before rerouting is taken into account. For a coalition origin e that fully bans exports of product k to Russia, $\tilde{\tau}_{eR}^{k\prime} \to \infty$. Partial bans raise the direct cost by a finite factor (Section 4.2.3). Bilateral costs that are not directly affected by the policy remain at their baseline values.

The direct-shock matrix $\tilde{\tau}'$ need not satisfy the TI. If, for some transshipment hub h, $\tilde{\tau}_{eR}^{k\prime} > \tilde{\tau}_{eh}^{k\prime} \tilde{\tau}_{hR}^{k\prime}$, the direct post-sanction cost cannot be the effective trade cost, and we replace it by the cheaper indirect cost.[49] Denote the resulting TI-consistent post-shock matrix by $\bar{\tau}_{ei}^{k\prime}$. By construction, no route through a third-country hub is cheaper than the corresponding bilateral cost recorded in $\bar{\tau}'$. This matrix gives the minimum post-sanction trade costs implied by the pre-war trade network, before we add the hub-specific wedges introduced below.[50] Without these wedges, the relative trade-cost change used in the counterfactual exercise would therefore be $\bar{\tau}_{ei}^{k\prime} / \tau_{ei}^{k}$.

This logic shows why we need to calibrate trade-cost *levels*. Knowing only that the direct coalition–Russia cost goes to infinity does not reveal whether Türkiye, China, the United Arab Emirates, or another country becomes the cheapest transshipment hub. Identifying

[48] This condition can be microfounded using link-level trade costs (Foellmi et al. 2024). In that case, the bilateral cost τ_{ei}^{k} is the cost of the cheapest available path from e to i, which is not necessarily the cost of a direct shipment. The TI therefore does not imply that all observed trade flows go directly from the origin to the destination. It implies only that the reduced-form bilateral trade costs in the gravity equation already incorporate any (cost-saving) indirect routes that firms use in equilibrium.

[49] Only countries outside the coalition can serve as intermediaries, and only for products that the origin may export to them. For instance, Belarus cannot serve as a hub for products that the EU also bans for exports to Belarus (Section 5).

[50] In general, the updating is repeated because the cheapest route to an intermediary may itself use another country. Iterating until no TI is violated incorporates one-hub and multi-leg paths into a TI-consistent post-shock bilateral cost matrix, and Foellmi et al. (2024) show that the procedure converges to a unique solution after a finite number of iterations. In our setting, the bans raise only the direct costs from coalition origins, while the links of the countries that can serve as intermediaries remain unchanged. Starting from a TI-consistent baseline, any route that uses multiple intermediaries can then be weakly shortened to a route through a single hub. The bilateral legs in $\bar{\tau}'$ may nevertheless themselves summarize multi-country paths (see Foellmi et al. 2024).

the lowest-cost hub and the corresponding increase in trade costs from rerouting requires the levels of the two relevant bilateral costs, τ^k_{eh} and τ^k_{hR}, for every potential hub. This is why the calibration below recovers a TI-consistent matrix of baseline trade-cost levels rather than relying only on relative changes (see Foellmi et al. 2024, for more details).

The TI also makes the distinction between trade diversion and transshipment clear. If Russia responds to an export ban by buying product k from a producer in a non-sanctioning country, this is standard trade diversion. If, instead, it keeps buying the coalition-origin product through an intermediary, it circumvents the ban through transshipment. So far, rerouting banned products requires covering only (indirect) baseline trade costs. However, circumventing an export ban involves additional costs, which may differ across hubs. Without such costs, the pre-war trade network would fully determine which hub is selected for a banned product, and exports of fully banned goods would drop much less than the triple-difference estimates in Section 3.1 imply. We therefore allow rerouting through a hub to cost more than the baseline trade costs imply, by a factor that differs across hubs, as we explain next.

4.2.2 Hub Capability

Because a full ban closes the direct link to Russia, banned goods reach Russia only through a hub, the country in which they are redirected (Section 2.4). Whether goods are re-exported or diverted en route, the redirection takes place where the goods physically are, so the hub lies on their physical route. How costly the redirection is depends on features of the hub country, such as its logistics infrastructure, its customs arrangements with Russia, and local enforcement. Transshipping a fully banned import of product k from coalition origin e through hub h costs

$$m^k_{h,eR} = \rho_h \, \bar{\tau}^{k\prime}_{eh} \bar{\tau}^{k\prime}_{hR}, \qquad \rho_h \geq 1, \tag{15}$$

where $\bar{\tau}^{k\prime}_{eh}$ and $\bar{\tau}^{k\prime}_{hR}$ are the baseline trade costs to and from the hub, and the wedge ρ_h captures the hub-specific cost of redirection. Both trade costs are reduced form and may summarize more complicated transportation paths, since we neither observe nor model every transport node along the route (see, e.g., Allen and Arkolakis 2022; Ganapati et al. 2024).

A lower ρ_h makes h more attractive for transshipment. Since $\rho_h \geq 1$ and the bans only raise costs, the TI implies that rerouting never makes a banned good cheaper than it was before the bans. With $\rho_h = 1$ for all h, banned goods are rerouted at baseline trade costs only, and the pre-war trade network alone determines which hub serves each banned product and at what cost. We refer to this case as the *model without hub wedges*.

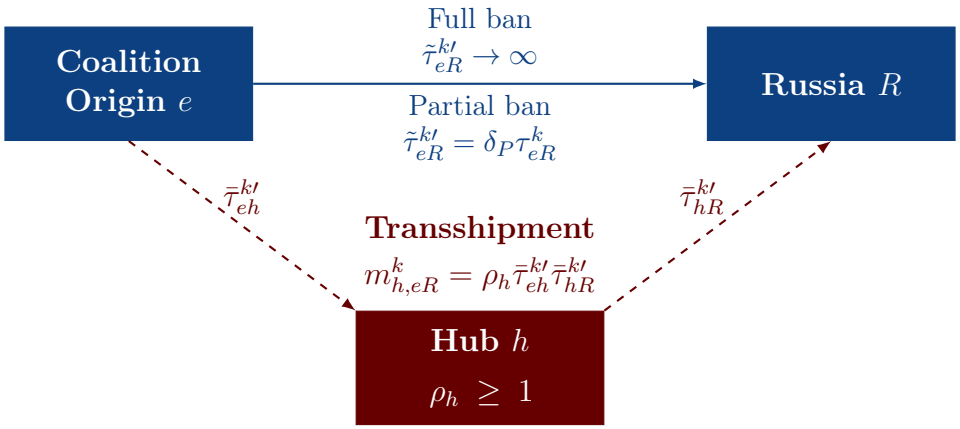

Figure 8. Transshipment through a Hub

Notes. When the direct export of product k from coalition origin e to Russia is fully banned, the product can be rerouted through an intermediary located in h. The two legs of this route have the TI-consistent costs $\bar{\tau}^{k\prime}_{eh}$ and $\bar{\tau}^{k\prime}_{hR}$, and potential hubs differ in the wedge $\rho_h \geq 1$ (equation (15)). Russia buys the product through the cheapest route. Under a partial ban, the direct link remains open at the cost $\delta_P \tau^k_{eR}$, and Russia buys the product through the cheaper of the direct link and the cheapest hub route (equation (17)).

For each origin and product, Russia buys through the cheapest hub, so the wedges and the baseline trade costs together determine which country serves as the hub. With $m^k_{(1),eR}$ denoting the lowest route cost across hubs, the trade cost of a fully banned import is

$$\tau^{k\prime}_{eR} = m^k_{(1),eR}, \tag{16}$$

and $m^k_{(1),eR} = \infty$ if no hub is available.[51] Figure 8 illustrates the resulting transshipment technology.

In the customs data, the hub is the dispatch country for re-exports and the first country outside the coalition on the inferred route for imports diverted en route (Section 2.4). Imports that cross from the Baltic states directly into Russia pass through no third country and have no counterpart in the model. We drop them, implicitly assuming that they reach Russia through the same hubs, in the same proportions, as the re-exports we observe.

The model routes all transshipped imports of an origin-product cell through a single hub, and in the data, one hub carries most of them. We refer to the exports of product k from origin e to Russia as the origin-product cell (e, k). Among the fully banned origin-product cells of the EU and the countries mirroring its sanctions that reach Russia through a hub, 53% use exactly one hub. When several hubs are used, the main hub accounts for a median share of 73% of the transshipped value. We therefore interpret the hub selected in the model as the main hub of an origin-product cell.

[51] In our main specification, rerouting earns no rents. Section 5 and Appendix F consider a thought experiment in which intermediaries in each hub instead charge a markup, the highest one they can charge without losing the trade flow to a competing route.

4.2.3 Partial Bans

Because the model is defined at the product level, a partially banned product can either still be exported directly to Russia at a higher cost or be transshipped, whichever is cheaper. A partial ban covers only some variants of a product (Section 2.1), whereas trade data, and hence the model, distinguish products but not variants. At the product level, a partial ban thus leaves part of the direct trade legal and bans the rest, which we capture by raising the direct trade cost by a factor $\delta_P \geq 1$, common to all partially banned products and origins. As with fully banned goods, the product can also be rerouted through a hub (equation (15)). Russia buys the product through the cheaper of the two routes, so its trade cost is

$$\tau_{eR}^{k\prime} = \min\left\{\delta_P\, \tau_{eR}^{k},\ m_{(1),eR}^{k}\right\}. \tag{17}$$

A partial ban therefore raises the trade cost by at most the factor δ_P, which we calibrate to the estimated trade cost increase for partially banned products (Section 4.3).

4.2.4 Solving the Model in Changes

The export bans affect the counterfactual equilibrium only through the trade costs that importers face, τ', which reflect both the bans on direct exports and the option to transship. Since hubs earn no rents from rerouting, labor remains the only source of income. Let $X_{ei}^{k\prime}$ denote importer i's counterfactual expenditure on product k from origin e. Labor-market clearing and income then take the same form as in the baseline,

$$w_e' L_e = \sum_{i=1}^{N}\sum_{k=1}^{K} X_{ei}^{k\prime}, \qquad X_i' = w_i' L_i, \tag{18}$$

and they again imply balanced trade.

Counterfactual equilibrium. For given trade-cost changes, we solve the counterfactual equilibrium in relative changes using the exact-hat-algebra approach popularized by Dekle et al. (2007). Let x' denote the counterfactual value of variable x, and let $\hat{x} := x'/x$. The trade-cost change entering the gravity equation is $\hat{\tau}_{ei}^{k} = \tau_{ei}^{k\prime}/\tau_{ei}^{k}$.

Given wages and trade costs, the product-level price changes are

$$\hat{P}_i^k = \left[\sum_{e=1}^{N} \pi_{ei}^{k}\left(\hat{w}_e \hat{\tau}_{ei}^{k}\right)^{-\theta^k}\right]^{-1/\theta^k}. \tag{19}$$

The corresponding group-price changes are

$$\hat{P}_i^g = \left[\sum_{k \in \mathcal{K}_g} \frac{X_i^k}{X_i^g} (\hat{P}_i^k)^{1-\sigma_g} \right]^{1/(1-\sigma_g)}, \tag{20}$$

and the aggregate price-index change is

$$\hat{P}_i = \left[\sum_{g \in \mathcal{G}} \frac{X_i^g}{X_i} (\hat{P}_i^g)^{1-\nu} \right]^{1/(1-\nu)}. \tag{21}$$

Counterfactual product-level trade shares are

$$(\pi_{ei}^k)' = \frac{\left(\hat{w}_e \hat{\tau}_{ei}^k\right)^{-\theta^k} \pi_{ei}^k}{\sum_{\ell=1}^N \left(\hat{w}_\ell \hat{\tau}_{\ell i}^k\right)^{-\theta^k} \pi_{\ell i}^k}. \tag{22}$$

Our nested demand system determines counterfactual product expenditure:

$$X_i^{k\prime} = \hat{X}_i X_i^k \left(\frac{\hat{P}_i^{g(k)}}{\hat{P}_i} \right)^{1-\nu} \left(\frac{\hat{P}_i^k}{\hat{P}_i^{g(k)}} \right)^{1-\sigma_{g(k)}}. \tag{23}$$

Bilateral expenditure is then

$$X_{ei}^{k\prime} = (\pi_{ei}^k)' X_i^{k\prime}. \tag{24}$$

Using the baseline identity $X_e = w_e L_e$, we can write equation (18) in changes as

$$\hat{w}_e X_e = \sum_{i=1}^N \sum_{k=1}^K X_{ei}^{k\prime}, \tag{25}$$

$$\hat{X}_i = \hat{w}_i. \tag{26}$$

The counterfactual equilibrium consists of wage changes $\{\hat{w}_i\}_{i=1}^N$ that satisfy equations (19)–(26), together with a numéraire normalization. These changes determine product and group prices, trade shares, and bilateral expenditure. We solve for the equilibrium using a tâtonnement algorithm (see also Alvarez and Lucas 2007).

Real income changes are given by $\hat{W}_i = \hat{X}_i / \hat{P}_i = \hat{w}_i / \hat{P}_i$. The nested demand structure also yields group-specific real absorption. Let $X_i^{g\prime} = \sum_{k \in \mathcal{K}_g} X_i^{k\prime}$. Then

$$\hat{Q}_i^g = \frac{\hat{X}_i^g}{\hat{P}_i^g} = \hat{W}_i \left(\frac{\hat{P}_i}{\hat{P}_i^g} \right)^{\nu}. \tag{27}$$

Real absorption of a group thus falls relative to real income, $\hat{Q}_i^g < \hat{W}_i$, whenever the group's price index rises relative to the aggregate price index. For a given rise in this relative price, the gap is larger the higher ν. In particular, $\hat{Q}_R^M$ and $\hat{Q}_R^C$ measure changes in Russia's real access to military-relevant and other critical goods.

Note that when setting $\sigma_g = \nu$ for all groups and $\rho_h = 1$ for all h, the framework nests the standard multi-product EK model with one CES nest, extended by the rerouting of banned goods at baseline trade costs only. In Section 4.3, we explain how we bring the model to the data.

4.3 Bringing the Model to the Data

We bring the model to the data in two stages. First, using 2019 data, we construct the pre-sanction economy: bilateral trade flows, total, group-, and product-level expenditure, and a TI-consistent matrix of bilateral, baseline trade-cost levels. Second, we calibrate the hub-specific wedges, ρ_h, and the partial-ban cost increase, δ_P. The distribution of hubs in the 2024 Russian customs data disciplines the relative wedges. The estimated effect of the full bans in Section 3.1 pins down the common level of the wedges, and an analogous estimate for the partial bans pins down δ_P. Post-sanction outcomes therefore enter the calibration only through ρ_h and δ_P.[52] Appendix E provides further details and lists the parameters in Table E.1.

Trade flows, production data, and elasticities We use bilateral trade flows from UN Comtrade at the 6-digit HS level and production data from the OECD Inter-Country Input-Output tables and the International Trade and Production Database for Estimation. These data and our cleaning steps yield a final sample of 74 countries, which account for 96% (98%) of Russia's total exports (imports), and 5,136 products. We assign the 5,136 products to the three groups based on existing lists of battlefield-relevant and strategic goods. For Russia, the three groups account for 1.6% (M), 30.7% (C), and 67.8% (O) of total expenditure. We cannot read X_i^k (i.e., product-level expenditure) directly from the data, because expenditure is not observable at this level of disaggregation globally. We therefore recover k-level expenditure (and, accordingly, domestic product-level trade) using the model's structure.

As is common in the literature, we do not estimate the elasticities ourselves. We take the trade elasticities, θ^k, from Fontagné et al. (2022), who estimate product-level trade elasticities using gravity regressions consistent with our setup. The resulting trade elasticities range from 1.5 to 44.1, with a median of 8.2. Russia can therefore replace a

[52] The country-selection rule also uses the 2024 customs data to ensure that empirically important hubs are represented in the model's country sample. All baseline flows, expenditures, elasticities, and trade-cost levels are constructed from 2019 or other pre-sanction sources.

sanctioned supplier much more easily for some products than for others. Within groups, we set $\sigma_g = 2.2$ for all three groups, in line with French (2016). Across groups, we set $\nu = 1.1$, close to the Cobb–Douglas case and half the within-group elasticity. Russia therefore substitutes much less easily across the three groups than within them.

Baseline trade costs Once a counterfactual trade-cost change ($\hat{\tau}$) is specified, the model can be solved in changes using baseline trade shares, as described in Section 4.2.4. The transshipment mechanism additionally requires bilateral trade-cost *levels*, because identifying the cheapest intermediary requires comparing alternative routes to Russia. We recover these levels in two steps. We first invert the gravity equation to obtain the bilateral trade barriers that rationalize the observed baseline trade shares and then use the triangle inequalities to recover the TI-consistent baseline trade-cost matrix used to compare routes after the export bans.

The gravity-implied barriers need not satisfy the triangle inequalities, because the bilateral term recovered from gravity combines route-related trade costs with other pair-specific barriers, such as bilateral preference shifters (Foellmi et al. 2024). To recover trade costs, we apply the algorithm from Foellmi et al. (2024, Section 4). It verifies the TIs, and if a TI is violated, it sets the updated trade cost equal to the minimum indirect cost. This procedure is repeated until there are no more TI violations.[53]

Post-sanction parameters We calibrate the hub-specific wedges, ρ_h, and the partial-ban cost increase, δ_P, to post-sanction outcomes for the EU and the countries that mirror its sanctions, since our sanctions data identify which of their products are fully and which are partially banned.[54] We write each wedge as the product of a common level, which is the same for all hubs, and a relative wedge. The relative wedges capture each country's relative capability in rerouting banned goods. A country with a lower relative wedge offers the cheapest route for more banned products and has a larger hub share. We therefore calibrate the relative wedges to the observed hub shares. The common level, in turn, determines how much more costly rerouting is on average than in the model without hub wedges, and we calibrate it to the estimated effect of the full bans.

Relative wedges. We measure hub shares in the data as the number of fully banned EU origin-product cells that reach Russia through each hub. Counting cells rather than values

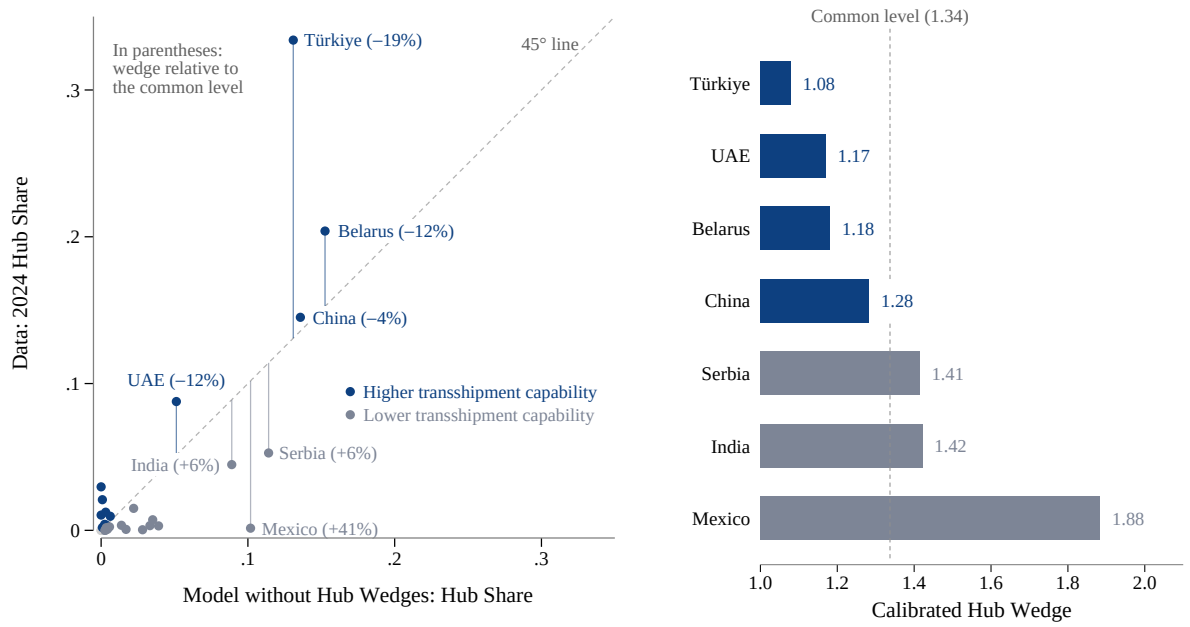

[53] The wedge between the initial value of trade barriers and the final value of trade costs can be interpreted as a bilateral preference shifter through the lens of standard gravity theory (cf. Foellmi et al. 2024). Because exact hat algebra conditions on the observed baseline trade shares, this residual need not be recovered separately. The levels τ_{ei}^k are needed only to determine rerouting opportunities and the corresponding trade-cost changes.

[54] From here on, "the EU" includes these countries (in our sample, Albania, Bosnia and Herzegovina, Iceland, Montenegro, North Macedonia, and Norway) when we refer to the bans and the exports they cover. Real-income results for the EU refer to its 27 member states.

matches the model, in which all transshipped exports of an origin-product cell go through the hub with the cheapest route, and the choice of hub depends on trade costs and the wedges but not on the value of the exports. Hubs in the data (Section 2.4) and in the model share the same definition: the country in which banned goods are redirected to Russia, which lies on their physical route, as in Figure 8. Because the hubs of imports diverted en route are inferred rather than directly observed (Section 2.4), we show in Section 5 that our results do not hinge on this imputation of the hubs by calibrating the relative wedges to re-exports alone.

Figure 9a compares the observed hub shares with those in the model without hub wedges, in which all hub wedges ρ_h equal one and each fully banned flow is rerouted through the hub with the cheapest route at pre-war baseline trade costs. Even though this model uses no information on the observed hubs (beyond the choice of the country sample), the pre-war trade network alone identifies most of the main hubs. The five largest hubs in the data are Türkiye, Belarus, China, the United Arab Emirates, and Serbia, and in the model without hub wedges, Mexico takes the place of the United Arab Emirates among them. Across all hubs, the correlation between the two sets of shares is 0.76. In both the data and the model without hub wedges, transshipment is highly concentrated among a few countries. The five largest hubs have a combined share of 82% in the data and 64% in this model. At the level of individual hubs, however, the model without hub wedges understates the roles of Türkiye, Belarus, and the United Arab Emirates and overstates those of Mexico, Serbia, and India. We then choose the relative wedges such that the model's hub shares match the observed ones as closely as possible (see Appendix E.4 for details). The hubs above the 45°-line in Figure 9a serve a larger share of the fully banned flows than the pre-war trade network alone predicts, and each of them receives a lower relative wedge than every hub below the line.

Common level. We choose the common level of the wedges such that the model reproduces the estimated effect of the full bans. Recall from Section 3.1 that fully banned flows fall by 85% relative to flows of never-sanctioned products. Through the lens of our model, this estimate measures the direct effect of the bans on the banned flows, before prices, wages, and other trade flows adjust. Through the gravity equation (11), the direct effect depends on how much more costly the cheapest hub route is than the pre-war direct route. Intuitively, more costly rerouting makes the banned goods more expensive relative to the goods of other suppliers, so Russia buys less of them. Specifically, the direct effect of the bans in the model reduces the banned flows by the same 85% on average (see Appendix E.4 for details). For the median fully banned flow, the cheapest hub route is then 69% more costly than the pre-war route. Figure 9b shows the calibrated wedges ρ_h of the hubs labeled in Figure 9a. In the counterfactuals, the calibrated wedges apply to the banned goods of all the coalition origins.

(A) Model without Hub Wedges vs. Data (B) Calibrated Hub Wedges

Figure 9. Transshipment Hub Shares and Calibrated Hub Wedges

Note: Panel 9a compares the hub shares in the Russian customs data for May to December 2024 (vertical axis) with those in the model without hub wedges (horizontal axis), in which all wedges equal one and banned goods are rerouted at pre-war baseline trade costs only. Both refer to the fully banned products of the EU and the countries that mirror its sanctions. A hub's share is the number of origin-product cells that it serves divided by the total across hubs. Section 4.3 explains how we measure hub shares in the data. The dashed line is the 45°-line. Every hub above the 45°-line (blue) has a lower calibrated relative wedge, and thus a higher transshipment capability, than every hub below it (gray). The numbers in parentheses show by how much the wedge of each labeled hub lies above or below the common level of the wedges, in percent. Panel 9b shows the calibrated wedges ρ_h of the labeled hubs, colored as in Panel 9a, and its dashed line marks the common level of the wedges, which equals their mean across all potential hubs.

Partial-ban cost increase. We calibrate δ_P to the estimated effect of the partial bans, in the same way as the common level of the wedges. A partial ban raises the cost of direct exports to Russia by the factor δ_P, and Russia buys the product through the cheaper of the direct link and the cheapest hub route (equation (17)). To estimate the effect of the partial bans, we rerun the triple-difference gravity specification in equation (2) with products that remain partially banned through December 2024 as the treated group, so that later upgrades to full bans do not contaminate the estimate. Relative to never-sanctioned products, these flows fall by 47% (see Appendix Figure E.1 for the event-study plot). Through the gravity equation (11), and given the product-level trade elasticities, this decline implies $\delta_P = 1.100$, which raises the cost of exporting the product directly to Russia by 10%. Since this cost increase is small relative to the cost of rerouting, Russia buys most partially banned goods directly, and only 7.4% of their 2019 value is rerouted in the model.

Untargeted fit. The relative wedges target only the aggregate hub shares of the EU. For the remaining coalition origins, the correlation between the model's and the observed hub shares rises from 0.39 in the model without hub wedges to 0.67 with the calibrated wedges (Appendix Figure E.2a). The main exception is Belarus, whose hub share for these origins is much larger in the calibrated model than in the data. For hub shares computed within each coalition origin, the correlation across origin-hub pairs rises from 0.55 to 0.90 (Appendix Figure E.2b). The calibrated wedges thus improve the fit beyond the aggregate hub shares they target. This is reassuring, since the counterfactuals apply the same wedges to the banned goods of all coalition origins. These comparisons use the same 2024 customs data as the calibration target and are therefore untargeted rather than out-of-sample.

5 The Aggregate Effects of Export Bans and Transshipment

This section asks how much the current export bans reduce Russia's imports and real income once transshipment is taken into account, and how much larger these effects would be without transshipment. We compare two post-ban equilibria. In the first, which we call *observed transshipment* (OT), Russia can still obtain fully banned coalition-origin goods through third-country hubs. It buys partially banned goods either directly, at a cost that is about 10% higher than before the bans (Section 4.3), or through a hub if this route is cheaper. In the second, which we call *no transshipment* (NT), the same bans apply, but no goods can be rerouted. Russia can then still buy partially banned goods directly, but fully banned coalition-origin goods are no longer accessible.

We apply the full and partial export bans in force by the end of 2024, accounting for differences in product coverage across coalition members. Partial bans apply to exports from the EU and the countries that mirror its sanctions, while we treat the restrictions of the other coalition members as full bans. Coalition countries cannot serve as intermediaries, including for products they do not themselves ban.[55] The export bans that the EU imposed on Belarus apply throughout, such that the goods they cover cannot reach Belarus, not even through third countries, and Belarus can never be used as a hub for them.[56]

All scenarios start from the same theory-consistent 2019 baseline without sanctions, for which we first solve the equilibrium with balanced trade. Like the other scenarios, observed

[55] This treats coalition membership as a commitment not to facilitate the circumvention of another member's export bans. We treat Ukraine as part of the coalition but assume that none of its goods reach Russia or Belarus, directly or through third countries.

[56] We do not model partial bans on exports to Belarus or the Belarus restrictions of the other coalition members.

transshipment is a counterfactual that applies the bans in force at the end of 2024. Because nominal flows are identified only relative to the model's numéraire, we report import effects as percentage changes in the corresponding flows' shares of world expenditure, which do not depend on this normalization. Although real income changes correspond to welfare changes in our model, sanctions are typically motivated by reasons beyond income effects, which is why we will explicitly call them real income losses throughout.

Russia's transshipment gain. Table 2 gives the main quantitative result. Under observed transshipment, the export bans reduce Russia's real income by 1.26% relative to the no-sanctions baseline. A loss of this size is substantial by the standards of quantitative trade models.[57] Without transshipment, the same bans would raise the loss to 1.66%. We call the difference between the two losses Russia's *transshipment gain*, since it measures what Russia gains from still being able to buy banned goods through hubs. In relative terms, the transshipment gain amounts to 32% of the loss under observed transshipment. We refer to this ratio as the *relative transshipment gain*. Put differently, transshipment spares Russia 24% of the loss that the bans would otherwise cause.

Russia's transshipment gain also has a money-metric interpretation. With homothetic preferences, the difference in equivalent variation between OT and NT, evaluated at baseline prices, is $X_R\left(\hat{W}_R^{\mathrm{OT}} - \hat{W}_R^{\mathrm{NT}}\right)$, where X_R is Russia's annual baseline expenditure. This amounts to approximately USD 4.5 billion per year in 2019 dollars. It is a welfare-equivalent amount rather than a fiscal transfer or a measure of resources directly available to the Russian state. To put the scale into perspective, this amount is numerically equivalent to the reported cost of about 130,000 Russian-produced strike drones, or to the first-year compensation packages of about 70,000 contract soldiers recruited in Moscow.[58]

Trade flows and strategic access. The trade responses explain why the sanctions can eliminate most targeted flows without producing a comparable fall in Russia's overall access to goods. Under observed transshipment, imports of fully banned coalition-origin products fall by 76%. Rerouted products retain their coalition origin in the model, so this decline already accounts for the goods that still reach Russia through hubs. For EU exporters, the decline is similar (Table 3). Both declines are smaller than the 85% estimated in Section 3.1, since the calibration matches that estimate only for the direct

[57] For comparison, using a related framework, Caliendo and Parro (2015) estimate that NAFTA's tariff reductions raised US welfare by 0.08%. See Costinot and Rodríguez-Clare (2014) for an overview of welfare magnitudes in quantitative trade models.

[58] We value drones at USD 35,000, the midpoint of reported unit costs of USD 20,000 to 50,000 for Russian-produced Shahed-type strike drones (CSIS, May 2025; Kyiv Independent, May 2025), and soldiers at the USD 60,000 of first-year pay that Reuters (July 2024) reports for contract soldiers recruited in Moscow. These prices are in 2024–2025 dollars, whereas the welfare equivalent is in 2019 dollars, so adjusting for inflation would raise the implied counts.

Table 2. The Aggregate Effects of the Sanctions on Russia

	Change in Imports			Change in Real Income, $\hat{W}$	
Scenario	Full	Partial	Total	Change	vs. Observed Transshipment
Observed Transshipment	-76%	-27%	-9%	-1.26%	
No Transshipment	-100%	-24%	-11%	-1.66%	+32%

Notes. This table reports how Russia's imports and real income change relative to the baseline without the sanctions. The import columns refer to Russia's imports of fully banned (Full) and partially banned products (Partial) from the coalition countries that ban them, and of all products (Total). Import entries are percentage changes in the corresponding flows' shares of world expenditure. Real-income changes are reported in percent, that is, $(\hat{W} - 1) \times 100$, and the last column reports the increase in Russia's real-income loss without transshipment, in percent of the loss under observed transshipment. Under "Observed Transshipment," fully banned coalition-origin goods can reach Russia through third-country hubs, and partially banned goods are bought directly at a higher cost or through a hub if that route is cheaper. Under "No Transshipment," fully banned coalition-origin goods no longer reach Russia, while partially banned goods can still be bought directly at the higher cost. The results are discussed in Section 5.

effect of the bans, before prices, wages, and other trade flows adjust (see Section 4.3). If banned goods could instead be rerouted at pre-war baseline trade costs only, as in the model without hub wedges (Section 4.2.2), imports of fully banned coalition-origin products would fall by only 37%, and Russia's real-income loss would be 0.58% instead of 1.26%. Ignoring the additional costs of circumvention would thus understate both the decline in banned trade and the costs of the bans for Russia. Even this smaller loss is substantial by the standards of quantitative trade models. It arises because, even at baseline trade costs, rerouting through a hub is typically more costly than shipping directly, and partial bans still raise the cost of direct exports.

The fully banned flows account for 27% of Russia's baseline imports. If no other import flow changed, their decline would reduce total imports by approximately 21%. Instead, total imports fall by only 9%, because Russia substitutes toward non-sanctioning origins and products that are not banned. Without transshipment, fully banned coalition-origin flows stop entirely, whereas the decline in total imports rises only from 9% to 11%. Imports of partially banned products even fall by less without transshipment than with it (Table 2). Intuitively, once fully banned goods can no longer be rerouted, Russia substitutes toward the products it can still buy, including the partially banned ones. At the same time, losing the hub routes hardly matters for partially banned goods, since only a small share of them is rerouted under observed transshipment.

The same pattern holds for military-relevant products. Fully banned coalition-origin flows account for 51% of Russia's baseline imports in group M and fall by 91% under observed transshipment. Total imports of military-relevant products, however, fall by only 12%, and Russia's real absorption of these goods, which includes domestic supply, falls by

Table 3. The Effects of the Sanctions on the EU

Country	Baseline Exports of Fully Banned Products (USD in M)	Change in Exports to Russia (%)						Change in Real Income (%)	
		Full		Partial		Total			
		OT	NT	OT	NT	OT	NT	OT	NT
EU27	58,838	-76%	-100%	-27%	-23%	-39%	-48%	-0.036%	-0.048%

Notes. This table reports changes in the exports of the EU members to Russia and in their real income under observed transshipment (OT) and no transshipment (NT), as defined in Table 2. The first column reports the baseline value of EU exports of fully banned products to Russia in millions of 2019 USD. Export changes are percentage changes relative to the baseline exports of fully banned (Full), partially banned (Partial), and all products (Total), summed over member states. They include goods rerouted through hubs, which keep their EU origin. Under NT, no fully banned EU goods reach Russia. Real-income changes refer to the median member-state change, $(\hat{W} - 1) \times 100$, so that the entry reflects a typical member state rather than the most exposed members. Appendix Table H.3 reports the member-state results.

3.6%.[59] The reason is that Russia shifts toward non-sanctioning or domestic suppliers and substitutes across products within group M. Moreover, because substitution across the three broad groups is harder than within them, Russia also does not reallocate much of its total expenditure away from military-relevant goods. Without transshipment, the decline in military-relevant real absorption rises only to 4.0%.

Impact on the EU. The real-income effects on the EU are modest relative to Russia's losses (Table 3). Under observed transshipment, the median member state loses 0.036% of real income, and the losses are concentrated among members with high pre-war exposure to Russia. Lithuania loses 0.46% and Estonia 0.33%, while the losses in Ireland and Portugal are close to zero (Appendix Table H.3).

Without transshipment, EU exporters lose all their sales of fully banned products to Russia, and the median member state's loss rises by 35%, somewhat larger than the corresponding 32% increase for Russia. Transshipment therefore lowers the losses on both sides in similar proportions, while the median member-state loss remains more than an order of magnitude smaller than Russia's in levels.

Robustness. Appendix Table H.1 recomputes the main comparison under alternative parameter choices and an alternative hub-share target. Unless noted otherwise, we recalibrate the hub wedges and the partial-ban cost increase in every specification. The

[59] Note that Russia's real absorption of military-relevant products may well have *increased* after the onset of the war and the introduction of Western export bans, as the war shifts Russian demand. This is explicitly not covered in our counterfactual analysis that focuses fully on the effects of the trade sanctions. We reconsider the sanction effect in a scenario with higher Russian military demand in the robustness section below.

main object of interest is the relative transshipment gain, which equals 32% in the main specification.

The demand-side elasticities, which are set rather than estimated, have little effect on this aggregate comparison. Varying the cross-group elasticity ν between 0.5 and 2.2, where $\nu = 2.2$ imposes equally easy substitution across and within groups, and lowering the within-group elasticity for military-relevant products to $\sigma_M = 1.2$ leaves the relative transshipment gain virtually unchanged. The nested structure matters more for how the sanctions affect the composition of Russian absorption than for this aggregate comparison (Appendix Table H.2). The harder it is to substitute across groups, the more of its spending Russia keeps on military-relevant goods as their prices rise, and the more it cuts back on the remaining goods. The effect of transshipment on military-relevant absorption, however, is similar in all of these variants.

The product-level home-share floor matters more. Because domestic product expenditure is recovered rather than directly observed, the main specification imposes a 10% lower bound on home shares (Appendix E.2). Lowering the bound to 5% changes both the baseline trade shares and, after recalibration, the hub wedges and the partial-ban cost increase. Russia's loss under observed transshipment then falls slightly, to 1.24%, while its loss without transshipment rises to 1.70%. Both changes raise the relative transshipment gain to 37%. The 10% bound is therefore conservative with respect to the size of the transshipment gain.

We further test whether the choice of the hub-share target drives our results. The main target also counts in-transit shipments, whose hub we infer from their point of entry into Russia (Section 4.3). When we instead calibrate the relative wedges to re-exports only, whose hub is the recorded dispatch country, the relative transshipment gain is 31%, close to the main specification.

Wartime conditions may shift Russian expenditure toward military-relevant goods relative to the 2019 baseline. We therefore triple Russia's demand weight for group M ($\hat{\alpha}_R^M = 3$) and first solve for the corresponding no-sanctions equilibrium. This raises the military-relevant group's baseline expenditure share from 1.6% to 4.5%. We then impose the export bans on this economy, holding the calibrated hub wedges and the partial-ban cost increase fixed. The greater weight on military-relevant goods raises Russia's losses modestly, to 1.32% with observed transshipment and 1.72% without it. This is due to military products being disproportionately target military products. The relative transshipment gain remains 31%, close to the main specification.

Finally, the product-level trade elasticities are based on long-run gravity estimates, while the relevant trade elasticities over the first years of the sanctions may be smaller. Boehm et al. (2023), for example, estimate a short-run elasticity that is less than half their

long-run value. Halving our trade elasticities raises Russia's loss to 2.29% under observed transshipment and to 2.92% without transshipment. Intuitively, when it becomes harder to substitute across source countries, a given increase in trade costs raises Russia's import prices by more. The relative transshipment gain, however, remains of a similar size, at 28%.

Across all specifications in Appendix Table H.1, Russia's imports of fully banned coalition-origin products fall by between 75% and 78% under observed transshipment, and the relative transshipment gain lies between 28% and 37%. Transshipment therefore remains quantitatively important throughout.

Effects on third countries. Third countries can benefit from the sanctions as Russia diverts its purchases from coalition suppliers toward their own products. Relative to the no-sanctions baseline, real income rises by 0.01% in Türkiye, 0.04% in the United Arab Emirates, and 0.08% in Serbia. These gains are larger without transshipment, because Russia then buys more of these countries' own products instead of rerouting coalition goods. Belarus, which is itself sanctioned throughout, loses real income in both scenarios, but less without transshipment.

In our main specification, hubs earn no rents from rerouting. What if they could instead charge a markup? To assess how much hubs could earn in this way, we consider a thought experiment in which each hub charges the highest markup it can without losing the trade flow to a competing route. Appendix F derives this markup and the resulting rents, and shows how we recalibrate the model so that it still matches the observed hubs and the estimated effects of the bans. Under observed transshipment, hubs then earn USD 2.00 billion, or 2.2% of Russia's baseline spending on fully banned coalition-origin goods, with the largest share going to Türkiye (Appendix Table F.1). Russia's losses barely change, at 1.26% with observed transshipment and 1.66% without it. This is because Russia's losses depend mainly on how much more it has to pay for banned goods, and the estimated effects of the bans pin down this price increase in both versions of the model. With markups, part of this increase goes to the hubs as rents instead of covering the cost of rerouting.

The scope of the current bans in perspective. The loss without transshipment takes the coalition's *current* product lists as given. If coalition countries instead stopped exporting every product to Russia, and no goods could be rerouted, Russia's real-income loss would reach 3.47% and its total imports would fall by 26%. The gap between this loss and the 1.66% loss that the current lists cause without transshipment reflects the products that these lists do not ban or ban only partially. How much the EU can add to Russia's loss by fully banning further products is one of the questions of the next section.

6 Sanctions Design: Strengthening Export Bans

Transshipment substantially weakens the current export bans. In this section, we compare ways of strengthening them and ask by how much measures to curb transshipment and changes in the product scope raise Russia's real-income loss.[60] We first take the current product lists as given and compare the closure of the routes that banned goods currently take, the shutdown of entire hubs, and the addition of new coalition members. We then ask how much the full bans added since July 2022 contribute to Russia's current loss, consider fully banning further products, and compare the costs of route closure and of these expansions to the EU members.

Route and hub closures make it harder to reroute goods that the current lists already ban. At most, they raise the cost of each restricted flow to its level without transshipment, so the loss without transshipment is the natural benchmark for these exercises. Recall that the difference between this loss and the loss under observed transshipment is Russia's transshipment gain (Section 5). We therefore report how much of this gain the route and hub closures eliminate.

6.1 Routes, Hubs, and Coalition Enlargement

The most direct response to transshipment is to target the routes that banned goods currently take. Enforcement of this kind is already an important part of the sanctions regime. In October 2024, for example, the US Treasury designated 275 individuals and entities across 17 jurisdictions for supplying Russia's military-industrial base or moving sanctioned goods through intermediary networks.[61] The EU's Common High Priority Items list similarly supports exporters' due diligence and the anti-circumvention work of customs authorities in partner countries.[62] Route-specific enforcement naturally targets the routes that banned goods currently take. A route that is unused today, however, may become attractive once these routes are closed.

Our model does not contain individual firms, so we represent route-specific enforcement at the origin-product-hub level. We close every hub route through which Russia buys banned coalition products under observed transshipment, both for fully banned products and for partially banned products that currently go through a hub. The affected goods then reach Russia through the cheapest remaining route, which for a partially banned product can also be the direct one. We thus consider a very strong form of route-specific

[60] As in Section 5, every exercise applies a policy to the 2019 economy. Throughout this section, "current" refers to observed transshipment with the bans in force at the end of 2024, and current exports are exports to Russia in this equilibrium, valued in 2019 dollars.

[61] See "Treasury Takes Aim at Third-Country Sanctions Evaders and Russian Producers Supporting Russia's Military Industrial Base," US Department of the Treasury, October 30, 2024.

[62] See the European Commission's List of Common High Priority Items.

enforcement, in which every route currently in use is identified and closed. In practice, closing a route requires monitoring trade flows through the hub and the cooperation of the hub country.

Russia's real-income loss rises from 1.26% to 1.42%, so even this strong form of enforcement eliminates only 41% of Russia's transshipment gain.[63] The effect is limited partly because routes that were not used before become the cheapest alternatives once the active ones are closed, and Russia can buy the banned goods through them.

A hub shutdown removes a country as an intermediary for every product, including on routes that are currently unused, but adds no restrictions to its own exports. A country that joins the coalition stops serving as a hub as well, and in addition restricts its own exports to Russia. Specifically, we compile a typical list of bans by non-EU coalition members and fully ban a product for a new member if it is banned by at least 3 of the 10 countries in group III of Table B.1, which yields 265 products (the median number of banned products among these ten countries is 220). Like the goods of the current coalition members, its newly banned goods can still reach Russia through the remaining hubs outside the coalition.[64]

Table 4 compares the two counterfactuals for the five countries that most often serve as hubs in the customs data (Türkiye, Belarus, China, United Arab Emirates, Serbia). The difference between the two shows how much a country's own exports matter beyond its role as a hub. For Türkiye, the hub shutdown alone accounts for 82.3% of the total effect of joining, and for the United Arab Emirates 77.0%, so most of the effect for these two countries comes from ending their role as intermediaries. For China, the hub shutdown accounts for only 7.6%, because restricting Chinese exports to Russia matters much more than removing China's role as an intermediary. Belarus and Serbia resemble China, although their hub role accounts for a larger part of the effect of joining, 38.7% and 44.5%, respectively.

If the five countries in Table 4 (Türkiye, Belarus, China, United Arab Emirates, Serbia) all stopped serving as hubs, Russia's real-income loss would rise to 1.48%, which eliminates 54% of Russia's transshipment gain. By contrast, coalition enlargement also restricts exports from additional origins. If these five countries joined the coalition together, Russia's real-income loss would rise to 2.04%, above the 1.66% loss without transshipment under the current restrictions. The joint effect exceeds the sum of their individual effects of joining in Table 4, since joint accession also removes the suppliers and hubs that remain available to Russia when each country joins alone. Whether such an enlargement

[63] If we close only the hub routes through which Russia currently buys banned EU products, Russia's real-income loss rises to 1.38%, which eliminates 30% of Russia's transshipment gain.

[64] When Belarus itself joins, the EU's bans on exports to Belarus remain in force.

Table 4. Closing Hubs and Enlarging the Coalition

Country	Increase in Russia's Real Income Loss			
	Hub Shutdown (pp)	Further Effect of Joining (pp)	Joining in Total (pp)	Hub Shutdown (% of Total)
Türkiye	0.080	0.017	0.097	82.3
Belarus	0.027	0.043	0.069	38.7
China	0.031	0.381	0.412	7.6
United Arab Emirates	0.015	0.005	0.020	77.0
Serbia	0.003	0.004	0.007	44.5

Notes. This table reports the effects of closing hubs and enlarging the coalition for the five countries that most often serve as hubs in the customs data (Section 4.3). The first three columns report increases in Russia's real-income loss in percentage points. "Hub Shutdown" is the increase relative to observed transshipment when the country no longer serves as an intermediary for any product, with no restrictions on its own exports. "Joining in Total" is the increase relative to observed transshipment when the country joins the coalition. It then no longer serves as a hub and fully bans its exports to Russia of every product that at least 3 of the 10 countries in group III of Table B.1 ban (265 products). When Belarus joins, the EU's bans on exports to Belarus remain in force. "Further Effect of Joining" is the difference between the two, that is, the additional effect of restricting the country's own exports. Components may not sum to the total because of rounding. The last column reports the hub shutdown as a percentage of the total effect of joining. The results are discussed in Section 6.1.

is feasible, however, depends on the willingness of all five countries to impose the bans themselves.

6.2 Full Bans Added since July 2022

Besides transshipment, the export bans leak because many products are banned only partially. Under a partial ban, Russia can still buy the product directly from the sanctioning countries, at a cost that is about 10% higher (Section 4.3). A full ban removes this direct option and leaves only the routes through third-country hubs. The EU has narrowed this leak over time by upgrading partial to full bans, and it has also fully banned products that were not banned before (Figure 1). Of the products that the EU fully bans at the end of 2024, 833 were only partially banned in July 2022 and 434 were not banned at all. To measure what these changes achieved, we return these products to their July 2022 status in the model.[65] Russia's real-income loss under observed transshipment would then be 24% smaller, at 0.96% instead of 1.26%. In other words, the full bans added since July 2022 raise Russia's loss by more than closing every hub route through which Russia currently buys banned coalition products would.

[65] We hold the hub-specific wedges, the partial-ban cost increase δ_P, the restrictions on all other products, the EU's bans on exports to Belarus, and the bans of the other coalition members at their current values.

6.3 Widening the Scope of the Export Bans

Beyond these past changes, the sanctioning countries can also fully ban further products. Unlike closing routes and hubs or enlarging the coalition, this does not depend on the cooperation of countries outside the coalition. Russia, however, can still buy the newly banned goods through these countries.

We evaluate expansions of the product list against two benchmarks. The first is the 1.42% loss after closing every hub route through which Russia currently buys banned coalition products. The second is the 1.66% loss that the current restrictions would cause without transshipment. This is also the loss that standard quantifications, which ignore transshipment, would predict for the current bans.

We consider additional bans by the EU and the countries that mirror its sanctions. Such bans can cover the 3,193 products that this group does not fully ban at the end of 2024, whether never-sanctioned or partially banned. Adding product k to the list means that all countries in the group, collected in the set $\mathcal{B}^k$, fully ban their exports of k to Russia, while their bans on exports to Belarus remain unchanged. The lists of the other coalition members remain unchanged, so Russia can still buy the newly banned products from them. Route closure, in contrast, applies to the banned goods of all coalition members. In this sense, the comparison with route closure is demanding for the product list.

Ranking products. These products differ in their importance for Russian expenditure, Russia's dependence on the sanctioning origins, their trade elasticities, and the routes available for rerouting around a new ban. We rank them by the first-order reduction in Russian real income per dollar of the group's current exports that a full ban would newly cover. The ranking thus favors products whose ban causes Russia the largest losses for a given value of newly restricted trade. This value is not the real-income cost to the sanctioning countries, which we later compute for the EU members in Section 6.4. The ranking is simple and in some sense one-dimensional, as it does not take into account that sanctions also pursue objectives other than lowering Russia's real income. Nevertheless, it gives a simple rule for the order in which products are added to the list. This allows us to quantify how much a targeted expansion of the product list can raise Russia's loss.

Russia's real income is $W_R = X_R/P_R$. Holding wages and nominal expenditure fixed at their levels under observed transshipment, we obtain, to a first order around this equilibrium,

$$\Delta \ln W_R = -\Delta \ln P_R \approx -\sum_k s_R^{k,\mathrm{OT}} \, \Delta \ln P_R^k,$$

where $s_R^{k,\mathrm{OT}} = X_R^{k,\mathrm{OT}}/X_R^{\mathrm{OT}}$ is product k's share in Russian expenditure under observed transshipment. A ban on product k alone therefore lowers Russian real income by approximately $s_R^{k,\mathrm{OT}}\,\Delta \ln P_R^k$.

Consider first the case in which the newly banned exports cannot be rerouted through third countries, while all other restrictions and routes remain as under observed transshipment. We label this case NR, for no rerouting. Let $\pi_{eR}^{k,\mathrm{OT}}$ denote origin e's share in Russia's expenditure on product k under observed transshipment and $b^k = \sum_{e\in\mathcal{B}^k} \pi_{eR}^{k,\mathrm{OT}}$ the combined share of the group. Holding wages fixed, equation (19) then implies

$$\Delta \ln P_R^{k,\mathrm{NR}} = -\frac{1}{\theta^k} \ln\bigl(1 - b^k\bigr)\,. \tag{28}$$

Under observed transshipment, the newly banned exports instead move to their cheapest hub route, and the partial-equilibrium price change becomes

$$\Delta \ln P_R^{k,\mathrm{OT}} = -\frac{1}{\theta^k} \ln\left[1 - b^k + \sum_{e\in\mathcal{B}^k} \pi_{eR}^{k,\mathrm{OT}} \left(\frac{m_{(1),eR}^k}{\tau_{eR}^{k,\mathrm{OT}}}\right)^{-\theta^k}\right]. \tag{29}$$

Here, $m_{(1),eR}^k$ is the cost of the cheapest hub route, and $\tau_{eR}^{k,\mathrm{OT}}$ is the cost at which the product currently reaches Russia, which for partially banned products already includes the effect of the partial ban. Unlike in the case without rerouting, Russia can keep buying the newly banned goods from their original suppliers through a hub. The product's price index therefore rises by less, and more so the cheaper the hub route is relative to the current cost.

In both cases, we divide the first-order loss by the group's current exports of product k to Russia, $v^k = \sum_{e\in\mathcal{B}^k} X_{eR}^{k,\mathrm{OT}}$. For products with positive exports, this yields the score

$$r_z^k = \frac{s_R^{k,\mathrm{OT}}\,\Delta \ln P_R^{k,z}}{v^k}, \qquad z \in \{\mathrm{NR}, \mathrm{OT}\}. \tag{30}$$

Ranking the products by r_{OT}^k yields the transshipment-adjusted list. Ranking them by r_{NR}^k yields the list that neglects transshipment, that is, the ranking implied by standard quantifications that ignore transshipment. Hausmann et al. (2024) rank products in a similar way, by the cost of a ban to Russia per dollar of foregone coalition exports, assuming that the bans cannot be circumvented. We use these scores only to rank the products and compute the effects of all packages in the full GE model.

Results. Figure 10 shows how Russia's real-income loss increases as more products from the transshipment-adjusted list are banned. The curve is steep at first and flattens out as the list grows. Intuitively, the list starts with the products whose ban imposes the

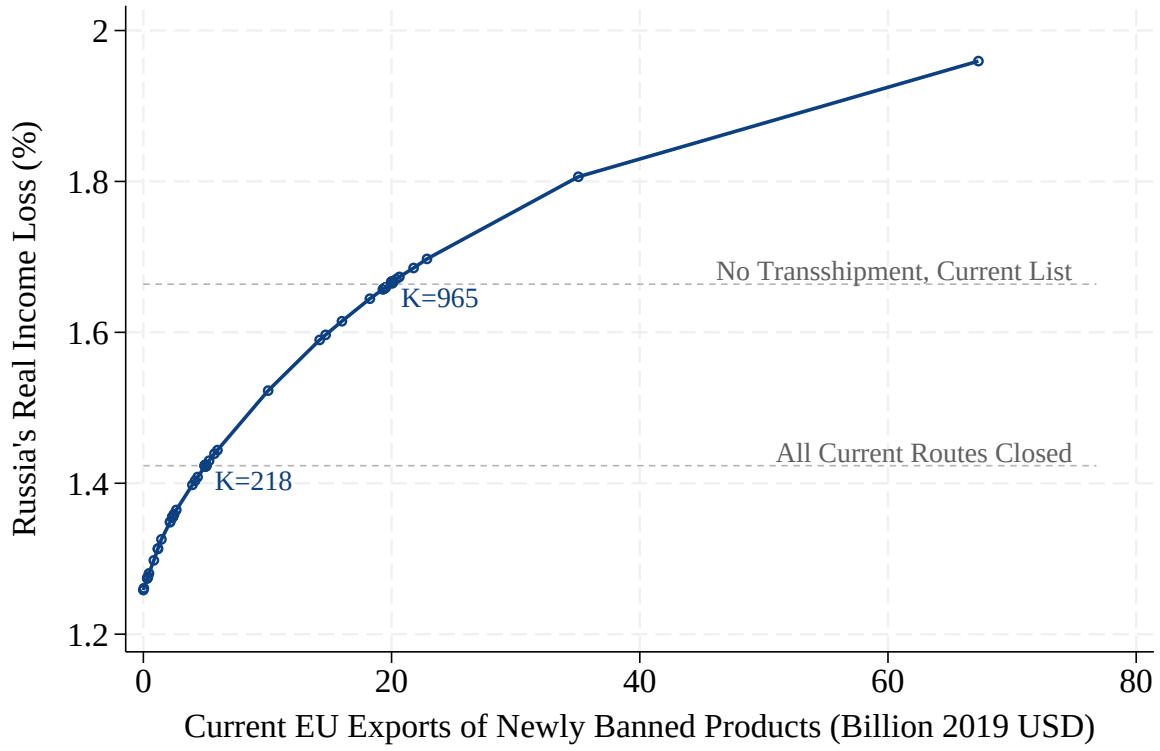

Figure 10. Widening the Product Scope under Observed Transshipment

Note: This figure reports Russia's real-income loss under observed transshipment, in percent of its real income without sanctions, as the EU and the countries that mirror its sanctions fully ban additional products from the transshipment-adjusted list on top of the current restrictions. The horizontal axis measures the current exports of the newly banned products from these countries to Russia, in billions of 2019 USD. The lists of the other coalition members remain unchanged. Both horizontal lines refer to the current bans of all coalition members. The upper line marks the loss that these bans would cause without transshipment, and the lower one the loss after closing every hub route through which Russia currently buys banned coalition products. The labels $K = 218$ and $K = 965$ mark the packages that reach these two levels. The results are discussed in Section 6.3.

largest loss on Russia per dollar of newly covered exports. Banning the first 218 of these 3,193 products raises Russia's loss to the level reached by closing every hub route through which Russia currently buys banned coalition products. These 218 products account for USD 5.0 billion, or 6%, of current EU exports to Russia. With the first 965 products, which account for USD 20.0 billion, or 25%, of current EU exports to Russia, the loss reaches the level that the current bans would cause without transshipment, even when transshipment remains possible.

How much does it matter that the products are chosen taking transshipment into account? We compare the transshipment-adjusted list with the list that neglects transshipment for the same budget, namely the current exports of the first 218 products of the transshipment-

adjusted list. With this budget, the list that neglects transshipment selects 124 products.[66] Under observed transshipment, these products raise Russia's loss by 16% less than the 218 products of the transshipment-adjusted list. The reason is that the two lists contain quite different products, as only 86 of the 124 products are also among the 218. The remaining 38, such as beer, vegetable seeds, and handbags, rank high only because the list ignores that Russia can keep buying them through third countries once they are banned. For the median of these products, existing routes absorb 70% of the price increase that a ban would cause without rerouting. The two lists become more similar as more products are added and coincide once all of these products are banned.

Our ranking relies on a first-order, partial-equilibrium score. To check how well it approximates the exact effects, we ban 18 products one at a time on top of the current restrictions and solve the full GE model for each.[67] The exact losses amount to 52% to 89% of the losses implied by the score. Part of this gap arises because the score holds Russia's expenditure shares fixed and thus ignores that Russia substitutes toward other products. The ranking of the products, however, is largely preserved, with a rank correlation of 0.88 between the score and the exact loss per dollar of newly covered exports. The order changes only among the first products, whose scores are close to each other. The score also predicts well which steps along the expansion path in Figure 10 raise Russia's loss the most. Across these steps, the rank correlation between the exact increase in the loss and the increase implied by the score is 0.992.

6.4 Comparing the Instruments

Table 5 compares closing every hub route through which Russia currently buys banned coalition products with fully banning the first 218 products of the transshipment-adjusted list. The two exercises generate almost the same additional loss for Russia, which makes their costs to the EU members directly comparable. Unlike the product expansion, however, closing routes depends on the cooperation of countries outside the coalition.

For the median EU member state, the product expansion has a lower additional real-income cost than route closure. This is consistent with the logic of the product ranking, which favors products whose ban causes Russia the largest losses for a given value of newly restricted trade.

[66] We add products from the top of this list as long as their combined current exports do not exceed those of the 218 products. If these products could not be rerouted, they would raise Russia's loss by 0.24 pp, more than the 0.20 pp that the 218 products would add without rerouting. Once rerouting is taken into account, however, their effect falls to 0.14 pp.

[67] These are the first eight products of the transshipment-adjusted list and those at ranks 12, 20, 35, 60, 100, 200, 400, 800, 1,600, and 2,800. Without dividing by exports, the rank correlation between the partial-equilibrium and the exact losses is 0.99.

Table 5. Comparing Ways to Strengthen the Export Bans

Instrument	Add. Russian Loss (% of Transship. Gain)	Add. Median EU Member Loss (% of Real Income)
Close current routes	+0.165pp (41%)	0.0043%
Transshipment-adjusted product expansion	+0.165pp (41%)	0.0021%

Notes. This table compares two ways of strengthening the export bans. Both raise Russia's real-income loss by about the same amount. "Close current routes" closes every hub route through which Russia buys banned coalition products under observed transshipment. The product expansion fully bans the first 218 products of the transshipment-adjusted list. These bans apply to exports to Russia from the EU and the countries that mirror its sanctions, while the lists of the other coalition members remain unchanged. The first column reports the increase in Russia's real-income loss relative to observed transshipment, in percentage points, and in parentheses as a share of Russia's transshipment gain. The second column reports the additional real-income loss of the median EU member state, in percent. Costs to the countries that mirror the EU sanctions and to the other coalition members are not included. The results are discussed in Section 6.4.

The main insight from these exercises is twofold. First, transshipment is quantitatively important, but curbing it is difficult. Closing every route currently in use eliminates only 41% of Russia's transshipment gain, since trade shifts to routes that were not used before. The accession of new coalition members can raise Russia's loss considerably more, in particular if a new member is an important supplier to Russia as well as a hub, but it requires these countries to impose the bans themselves. Second, the product scope of the bans is quantitatively important as well. The product list is under the direct control of the sanctioning countries. The full bans added since July 2022 already account for 24% of Russia's current loss. Fully banning a targeted set of further products raises Russia's loss about as much as closing every route currently in use. With 965 products, the loss reaches the level that the current bans would cause without transshipment. Whether the costs of these measures are worth bearing depends on the geopolitical objective and lies outside the scope of our analysis.

7 Conclusion

Discriminatory trade policy invites transshipment, and the EU export bans on Russia show how much it matters. Linking Russian customs records with new data on the bans, we find that banned EU goods worth about 20% of pre-war imports keep reaching Russia, almost always through a hub outside the EU. The bans act like a 69% tariff rather than a ban, and stricter enforcement shifted sales to third-country intermediaries rather than stopping them. In a general-equilibrium model disciplined by these facts, the same bans would raise Russia's real-income loss by 32% without transshipment. Closing every route currently in use would recover only 41% of Russia's gain from transshipment, because trade moves to routes not yet used. Enlarging the coalition does more, since a new member

stops serving as a hub altogether: if the five largest hubs joined, Russia's loss would exceed the loss the current bans would cause without transshipment.

Our analysis applies the bans to an economy calibrated to 2019 and holds the hubs' transshipment capabilities fixed. In practice, enforcement closes routes and intermediaries build new ones over time, and modeling these dynamics is a natural next step. The framework also extends to other discriminatory barriers that can be circumvented through third countries, such as targeted tariffs, where transshipment typically requires misdeclaring the origin of goods.

14th package	24 Jun 2024	dual-use/high-tech*, industrial capacity*, strategic goods†

Note: * export restriction; † import restriction. "Industrial capacity" refers to goods that could contribute to the enhancement of Russia's industrial capacities. The adoption date is the date of the Council regulation and generally differs from the product-specific entry-into-force dates used in the analysis. Source: Council regulations amending Regulation (EU) No 833/2014; BAFA overview of restrictive measures against Russia.

Coverage Table .2 reports the number of HS2017 products by ban status at two points in time. In July 2022, export bans covered 50.5% of all HS6 products, but most of them only partially. By December 2024, the share of fully banned products had tripled to 37.5%, while the share of partially banned products had fallen to 23.0%. Figure 1 in the main text shows that this reversal reflects both the extension of the bans to new products and the conversion of partially into fully banned products, as subsequent packages restricted the remaining CN8 lines within already affected HS6 products. Figure .1 reports the coverage by sector.

Table .2. Coverage of EU Export Bans on Russia (HS2017 Six-Digit Products)

	July 2022			December 2024		
	Full	Partial	Total	Full	Partial	Total
Number of products	683	2,023	2,706	2,010	1,163	3,173
Share of all HS6 products (%)	12.7	37.7	50.5	37.5	23.0	60.5

Note: Products are HS2017 six-digit codes, classified according to Steps 1–6. A product is counted in a given month if the ban is in force for at least 15 days of that month.

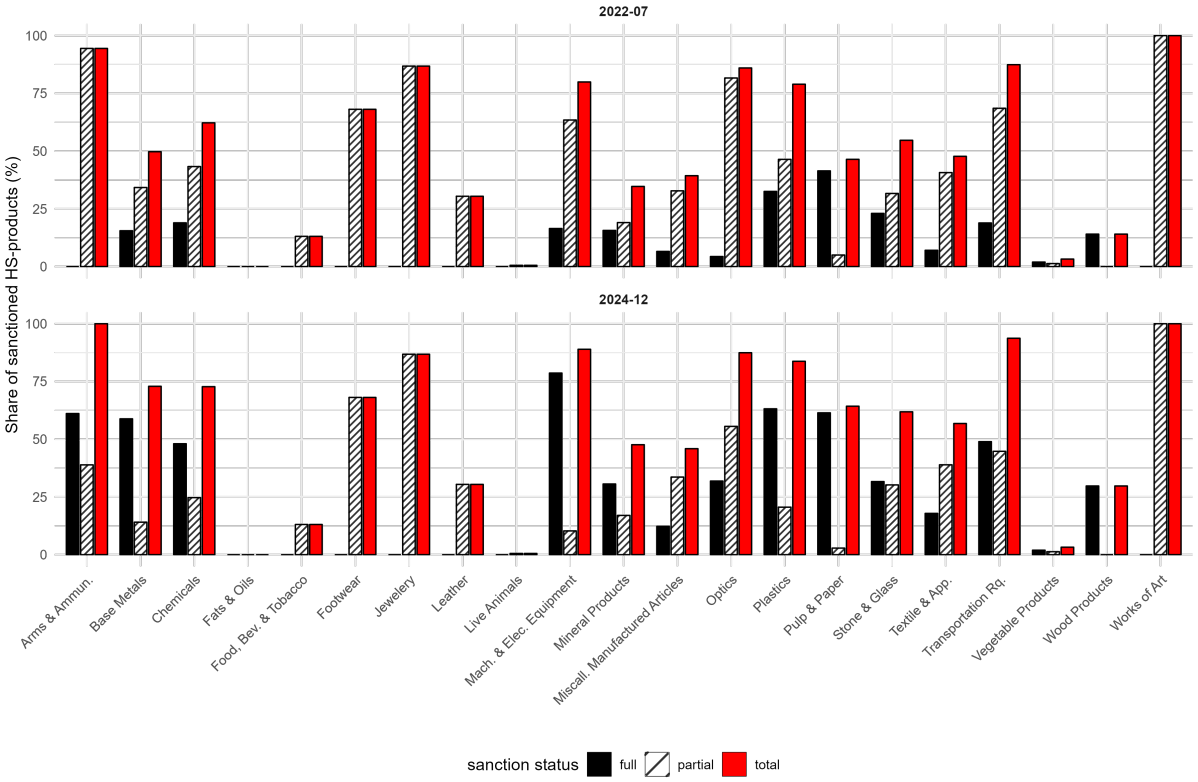

Figure .1. EU Export Bans By Sectors

Note: The figure reports, by sector, the share of HS6 products covered by EU export bans. Black bars indicate fully banned products, striped bars partially banned products, and red bars total banned products. The upper panel shows coverage as of July 2022, and the lower panel as of December 2024.

A Comparison of new EU Export Ban Data with Existing Sources

Existing product-level sanctions data are constructed either from the Council regulations and their annexes (e.g., Crozet and Hinz 2020; Flach et al. 2024) or from the Global Trade Alert. Our data differ from these sources along two dimensions.

Legal scope within tariff lines Existing data record a product as sanctioned whenever it appears in a regulation, typically at the HS6 level, and do not distinguish full from partial bans. Products restricted only through *ex* entries or through the dual-use regime are thus treated in the same way as products whose export is prohibited altogether, although most of their trade remains legal. Separating the two categories has three advantages. First, it avoids classifying legal shipments as sanctioned trade, which would bias estimated ban effects toward zero and mechanically overstate evasion. Second, it allows the effects of bans to be estimated separately by stringency. Fully banned products should cease to be exported directly once the ban takes effect, whereas partially banned products may continue to be exported and are subject to different adjustment and rerouting margins. Figure 2 shows that direct EU exports of fully banned products indeed drop to zero, while exports of partially banned products decline but do not collapse. Third, because the classification starts at the CN8 level, which is the level of EU customs declarations and firm-level trade data, it can be linked to transaction-level data without discarding the information on which variants within a product are restricted.

Product codes for verbally defined regimes The Council regulations do not provide product codes for all regimes. Annex I of Regulation (EU) 2021/821, for instance, describes dual-use items only verbally. Data built from the legal texts alone must either omit these products or assign codes by hand. TARIC translates the descriptions into CN8 codes, so our data cover the dual-use and high-tech regime, the largest regime by number of restricted products, without manual assignment, and the annexes are needed only to determine the scope and the regime of each line.

Timing of the bans Existing data date bans by the adoption or publication date of the regulation, which is common to all products in a package. The date from which a ban is applied at the border, however, often differs from the adoption date because regulations grant transition periods for the execution of existing contracts. For example, Regulation (EU) 2022/328 of 25 February 2022 prohibits the export of oil-refining technology, but allows the execution until 27 May 2022 of contracts concluded before 26 February 2022. Such transition periods vary across products within the same package. Dating bans by the adoption date would assign treatment before the ban is legally binding, so that continued exports during the transition period would be interpreted as a weak response to the ban or as evasion. Using product-specific EIF dates aligns the treatment with legal enforceability, allows us to distinguish anticipation, transition, and post-EIF dynamics in the event-study design, and avoids bias from heterogeneity in transition periods across products.

Validation against the Global Trade Alert To assess how our data relate to existing sources, we compare our classification of EU export bans with the EU export bans recorded in the GTA for the same period (until June 2024). Of the 2,780 HS6 products recorded as banned by the EU in the GTA, 2,667 can be matched to our data. Among these matched products, 78.4% (2,091) are fully banned and 21.3% (569) are partially banned in our data, while 0.3% (7) are not restricted, which reflects differences between the implementation date in the GTA and the EIF date in TARIC. The remaining 113 products (4.1%) are concentrated in chemicals (HS chapters 28, 29, and 38) and are restricted by regulations adopted after our sample period, such as Council Regulation (EU) 2025/1494 of 18 July 2025. The two classifications thus largely agree on which products are restricted, with a Jaccard similarity of 0.74 and a correlation of 0.75 (Table B.2). The main difference is that about one in five products that the GTA records as sanctioned is only partially banned according to the legal texts, and would be misclassified as fully banned when relying on the GTA alone.

B Export Bans of the Coalition

In the counterfactual exercises (Section 4.3), we need to specify which countries banned which products. These countries form the *coalition*. This section describes how we define the coalition (Section B.1), how we measure the export bans of non-EU coalition members (Section B.2), how similar their regimes are to the EU regime (Section B.3), and how we construct the EU export bans on Belarus, which we need to block transshipment via Belarus (Section B.4).

B.1 Coalition Membership

Step 1: US EAR exemption list Following Li et al. (2024), we start from the countries exempted from US licensing requirements for exports to Russia, as listed in Supplement No. 3 to Part 746 of the Export Administration Regulations (EAR). The list includes countries that "have committed to implementing substantially similar export controls" on Russia. It comprises 38 countries: the EU-27 and Australia, Canada, Iceland, Japan, Liechtenstein, New Zealand, Norway, South Korea, Switzerland, Taiwan, and the United Kingdom. We add the United States itself.

Step 2: Alignment with the EU regime The EU does not prescribe how third countries implement its restrictive measures, and three forms of alignment have emerged: (i) *coordinated alignment*, under which candidate and associated countries adopt EU sanctions as part of aligning with the EU acquis; (ii) *self-constraint*, under which countries

voluntarily adopt EU sanctions without a legal obligation, often supported by dialogue mechanisms (e.g., Norway); and (iii) *à la carte alignment*, under which countries selectively and autonomously adopt EU measures (e.g., Switzerland). The Council regularly publishes statements on the alignment of third countries with each sanctions package against Russia. Albania, Bosnia and Herzegovina, Iceland, Liechtenstein, Montenegro, North Macedonia, Norway, and Ukraine are consistently listed as aligning with the packages.[68] We add these countries to the coalition and assume that the EU regime applies to them identically, i.e., we assign them the EU classification, $S_{ekt} = S_{kt}$ for every mirroring country e. We also add Singapore, which has imposed its own export controls on Russia.

Table B.1 lists the resulting coalition in three groups: the EU-27 (group I), the countries that mirror the EU sanctions (group II), and the other sanctioning countries (group III).

Table B.1. Sanctioning Coalition Countries

I. EU-27			
AUT — Austria	BEL — Belgium	BGR — Bulgaria	CYP — Cyprus
CZE — Czechia	DEU — Germany	DNK — Denmark	ESP — Spain
EST — Estonia	FIN — Finland	FRA — France	GRC — Greece
HRV — Croatia	HUN — Hungary	IRL — Ireland	ITA — Italy
LTU — Lithuania	LUX — Luxembourg	LVA — Latvia	MLT — Malta
NLD — Netherlands	POL — Poland	PRT — Portugal	ROU — Romania
SVK — Slovakia	SVN — Slovenia	SWE — Sweden	
II. Mirrors EU sanctions			
ALB — Albania	BIH — Bosnia & Herzegovina	ISL — Iceland	LIE — Liechtenstein
MKD — North Macedonia	MNE — Montenegro	NOR — Norway	UKR — Ukraine
III. Other sanctioning countries			
AUS — Australia	CAN — Canada	CHE — Switzerland	GBR — United Kingdom
JPN — Japan	KOR — South Korea	NZL — New Zealand	SGP — Singapore
TWN — Taiwan	USA — United States		

Note: The table distinguishes three groups of sanctioning countries. The first group comprises the EU-27 member states. The second group includes non-EU countries that closely mirror the EU sanctions regime and for which the same sanctions are applied consistently. The third group consists of non-EU coalition countries that have imposed their own sanctions regimes on Russia, which differ to varying degrees from the EU regime.

B.2 Export Bans of Non-EU Coalition Members

Data source For the coalition members in group III of Table B.1, we draw product-level export restrictions from the Global Trade Alert (GTA) database. The GTA records state interventions together with the implementing jurisdiction, the affected jurisdictions, the affected HS6 products, and the implementation date.

[68] See, e.g., the Council alignment statement of December 8, 2025.

Processing of the GTA data We process the GTA intervention data in the following steps:

1. We reshape interventions affecting several products into long format, with one row per intervention and HS6 product, and harmonize product codes to six digits.
2. We keep interventions whose affected jurisdiction is Russia and whose implementing jurisdiction is a coalition member.
3. We keep interventions classified as discriminatory ("red") in the GTA evaluation and applying to all firms or to individual firms.
4. We keep export bans and export licensing requirements, and drop export-related non-tariff measures and interventions of undefined type.
5. We keep interventions implemented before December 2024 and drop observations without affected products.

This yields an indicator $G_{ek} = 1$ if coalition member e restricts exports of HS6 product k to Russia according to the GTA, together with the implementation date t_{ek}^{impl}.

Timing and definition of a ban for other coalition members The GTA reports implementation dates rather than EIF dates and does not distinguish full from partial bans. We therefore combine the GTA listing with the observed response of exports. Let X_{ekt} denote exports of product k from e to Russia in month t and $\overline{X}_{ek}^{\text{pre}}$ their average in the pre-invasion period. Product k is classified as banned for country e from month

$$T_{ek} = \min \left\{ t \geq t_{ek}^{\text{impl}} : X_{ekt} < 0.1\, \overline{X}_{ek}^{\text{pre}} \right\} \quad \text{if } G_{ek} = 1 \text{ and } \overline{X}_{ek}^{\text{pre}} > 0, \tag{31}$$

and from $T_{ek} = t_{ek}^{\text{impl}}$ if $G_{ek} = 1$ and e did not export k to Russia in the pre-period. The export criterion plays the same role as the full-ban classification for the EU: it retains products for which the listed restriction is binding for the bulk of trade. Because the GTA does not distinguish full from partial bans, we do not use these countries in analyses that require this distinction, such as the triple-difference event-study design in Section 3.1.

Coverage by the EU regime The EU regime broadly encompasses the products banned by the other coalition members. For all coalition members except Japan, Australia, and New Zealand, at least 88% of the products they ban are also banned by the EU, which justifies treating them as part of a common coalition. With roughly 3,000 banned products, the EU's coverage nevertheless extends well beyond that of its coalition partners.

B.3 Similarity of Sanctions Regimes

Measures To compare the product scope of coalition members' export bans with the EU regime, we compute two measures for each pair of jurisdictions (e, e'), based on binary indicators b_{ek} equal to one if e restricts exports of HS6 product k to Russia. The Jaccard similarity,

$$J_{ee'} = \frac{|\mathcal{K}_e \cap \mathcal{K}_{e'}|}{|\mathcal{K}_e \cup \mathcal{K}_{e'}|}, \tag{32}$$

where $\mathcal{K}_e = \{k : b_{ek} = 1\}$, measures the share of products restricted by at least one of the two jurisdictions that are restricted by both. It ignores products restricted by neither jurisdiction and is therefore not driven by the large number of jointly unrestricted products. The Pearson correlation of b_{ek} and $b_{e'k}$ across products (the ϕ coefficient) additionally accounts for jointly unrestricted products, but is sensitive to differences in the number of restricted products between the two jurisdictions. Table B.2 reports both measures between our EU classification and each coalition member.

Table B.2. Similarity between EU Export Bans and Coalition Members' Export Bans

Country	Jaccard similarity	Correlation
EU (GTA)	0.738	0.751
Switzerland	0.565	0.522
United States	0.474	0.356
South Korea	0.451	0.461
Japan	0.388	0.052
Australia	0.372	−0.013
Canada	0.307	0.234
United Kingdom	0.297	0.150
New Zealand	0.282	−0.255
Singapore	0.025	0.110

Note: The table compares fully banned HS6 products in our EU data with the HS6 products restricted by each jurisdiction in the GTA (export bans and export licensing requirements), for restrictions in force by July 2024. "EU (GTA)" refers to the EU export bans as recorded in the GTA. Rows are sorted by Jaccard similarity.

The Jaccard similarity is highest for Switzerland, the United States, and South Korea. Low correlations combined with moderate Jaccard similarity, as for Japan and Australia, arise when one jurisdiction restricts many more products than the other.

Dual-use items The GTA records restrictions of dual-use items only incompletely, because most national export-control lists, like the EU list, define items by technical description. To assess whether the EU dual-use list approximates those of coalition members, we compare the codes in the national export-control lists. Table B.3 shows that between 95.9% and 100% of the 344 EU codes appear in each national list, and that, with the exception of the United States, 86% to 93% of the codes in each national list appear in the EU list. The US list is substantially broader.

Table B.3. Overlap of Dual-Use Lists

	EU codes in national list		National codes in EU list	
Country	Number	Share of EU codes (%)	Total national codes	Share in EU list (%)
New Zealand	344	100.00	399	86.22
Switzerland	341	99.13	384	88.80
United Kingdom	341	99.13	368	92.66
Taiwan	339	98.55	363	93.39
Singapore	337	97.97	364	92.58
United States	332	96.51	658	50.46
Australia	330	95.93	362	91.16

Note: Codes refer to entries of the national export-control lists (ECCN-type classifications). The EU list contains 344 codes.

B.4 EU Export Bans on Belarus

The EU has also extended its sanctions regime to Belarus in response to the country's involvement in Russia's military aggression against Ukraine. This matters for our quantification, because in the model we block transshipment via Belarus for the products that are also banned vis-à-vis Belarus (Section 4.3).

Legal background Council Regulation (EC) No 765/2006 of 18 May 2006 established the framework of EU restrictive measures against Belarus, originally in response to human rights violations and the repression of civil society. Council Regulation (EU) 2022/355 of 2 March 2022 amended it in response to Belarus's involvement in Russia's military aggression against Ukraine, introducing export restrictions on dual-use goods and technologies and on items that could contribute to Belarus's military, technological, defense, and security development. Subsequent amendments, including Regulations (EU) 2022/398 and 2023/1594, extended the restrictions and added measures against the circumvention of existing sanctions, among them export bans on goods and technologies for the aviation and space industries.

Measurement We construct the Belarus data from TARIC following Steps 1, 5, and 6 of Section **??**, including the inheritance rule. Two differences apply. First, we date restrictions by the implementation date of the measures rather than by the EIF date. Second, we do not classify CN8 lines as partially banned on the basis of *ex* entries or the dual-use regime. A product is therefore partially banned only if some, but not all, of the CN8 lines within an HS6 product are restricted. Since implementation dates precede EIF dates when transition periods apply, this classification is, if anything, too broad, and the resulting overlap with the Russia regime is an upper bound.

Coverage Table B.4 reports the level of the product code at which the restrictions are defined in TARIC. As of July 2022, 2,117 of 9,771 CN8 lines (21.7%) are restricted. Most of these restrictions are defined at the four-digit or eight-digit level, so that the inheritance rule is quantitatively important. At the HS6 level, 1,195 products are restricted in July 2022 (1,063 fully and 132 partially) and 1,299 products in December 2024 (1,156 fully and 143 partially). Figure B.1 reports the coverage by sector. The overlap with the Russia regime is limited: 29% of the HS6 products fully banned vis-à-vis Russia by July 2022 are also fully banned vis-à-vis Belarus, and 38% by December 2024.

Table B.4. EU Export Bans on Belarus by Level of Legal Definition (CN8 Lines)

	July 2022		December 2024	
Level of restricted code	CN8 lines	Share (%)	CN8 lines	Share (%)
Four-digit heading	975	9.98	1,085	11.10
Six-digit subheading	159	1.63	177	1.81
Eight-digit CN line	983	10.06	1,006	10.30
Total	2,117	21.67	2,268	23.21

Note: The table reports the number of CN8 lines restricted vis-à-vis Belarus, by the level of the product code to which the TARIC measure is attached. Restrictions at the four- and six-digit level apply to all CN8 lines below them (inheritance rule). Shares refer to all 9,771 CN8 lines.

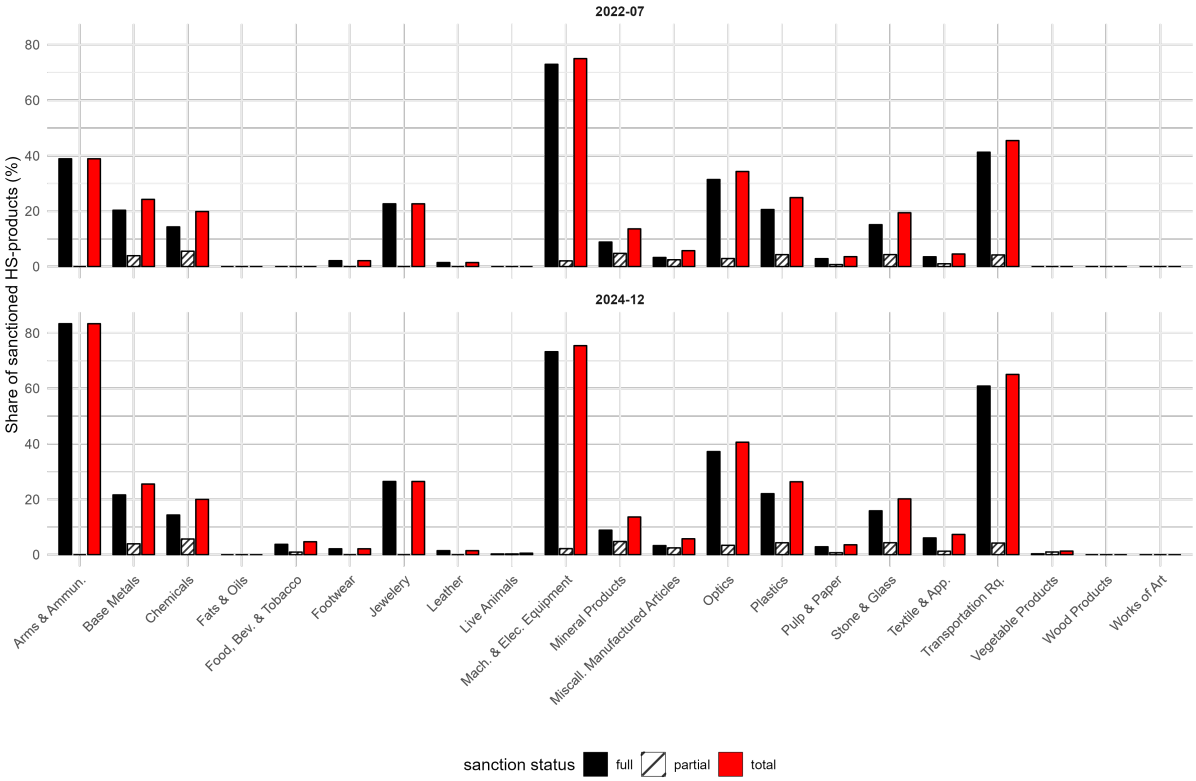

Figure B.1. Sectoral Coverage of EU-BLR sanctions by status and EIF date

Note: This figure reports, by sector, the share of EU-sanctioned products vis-à-vis Belarus at the 6-digit HS2017 level, distinguished by sanction status. Black bars indicate the share of fully sanctioned products, striped bars the share of partially sanctioned products, and red bars the total share of sanctioned products. The upper panel includes all sanctions that came into force by July 2022, while the lower panel includes all sanctions in effect by December 2024.

C Validation of Russian Customs Data

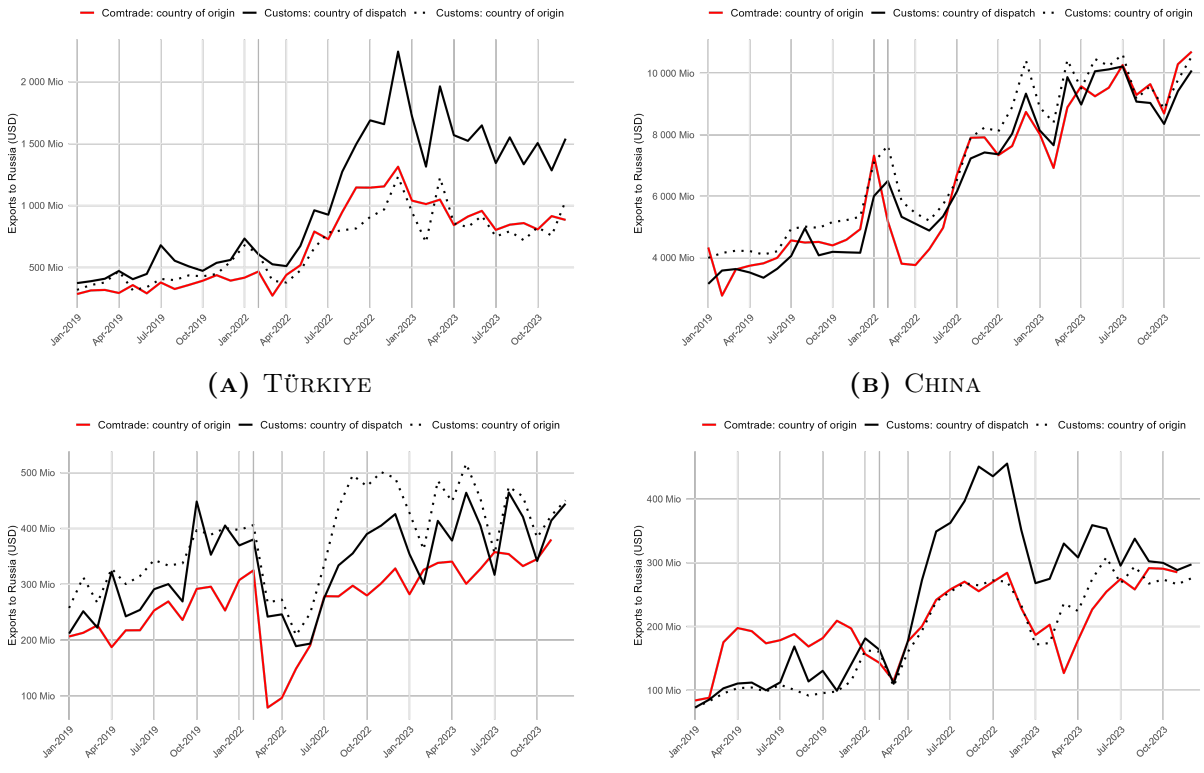

This section assesses the quality of the Russian customs data by comparing Russian import records with mirror export data from UN Comtrade, which report exports to Russia as declared by the partner countries. We proceed in two steps. Section C.1 compares the two sources for the largest exporters to Russia outside the sanctioning coalition. Section C.2 turns to a systematic comparison across all partners and sectors, which adjusts for the reporting quality of the mirror reporter and benchmarks Russia against other importers. Section C.3 examines whether Russia's reporting gap has widened specifically in the products most exposed to sanctions.

C.1 Comparison for Large Non-Coalition Exporters

Comparisons with mirror data are uninformative for sanctioning countries, for which discrepancies are expected by construction and are precisely how we measure evasion. We

therefore focus on non-sanctioning countries, whose exports to Russia remain legal and unrestricted and for which there is no incentive to misreport trade. If Russian customs data were systematically manipulated, imports from these countries would also diverge from partner-reported exports. We examine the four largest post-invasion exporters to Russia outside the sanctioning coalition for which UN Comtrade data are available; additional examples are reported in Figure C.2.

Figure C.1 shows that, for Türkiye, China, and Uzbekistan, UN Comtrade mirror exports closely track Russian customs imports by country of origin. For India, Comtrade flows are systematically lower, but this pattern predates the full-scale invasion of Ukraine in February 2022 and likely reflects known limitations of mirror statistics, such as valuation differences between CIF and FOB prices or reporting thresholds, rather than manipulation of the customs data.

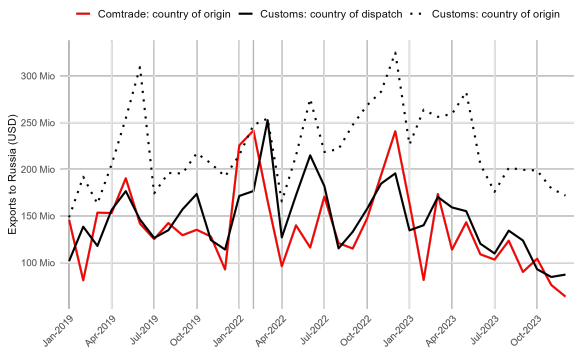

(A) Türkiye (B) China

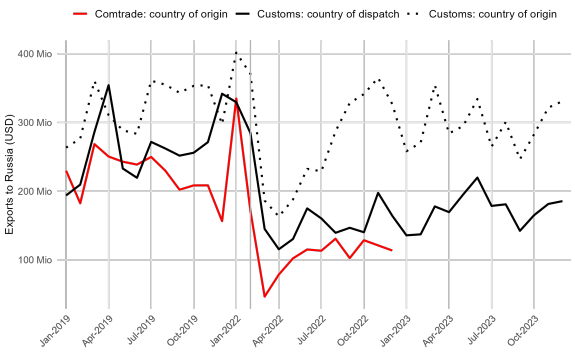

(C) India (D) Uzbekistan

Note: The figure compares Russian customs imports with mirror exports to Russia reported in UN Comtrade, by month, year, and partner country. Data are shown for 2019 and for 2022–2023 for the largest exporters to Russia outside the sanctioning coalition, for which UN Comtrade data are available. Trade values are expressed in millions of US dollars.

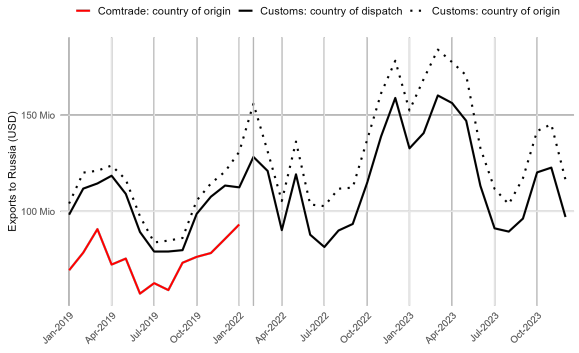

Figure C.1. Comparison of UN Comtrade and Russian Customs Data

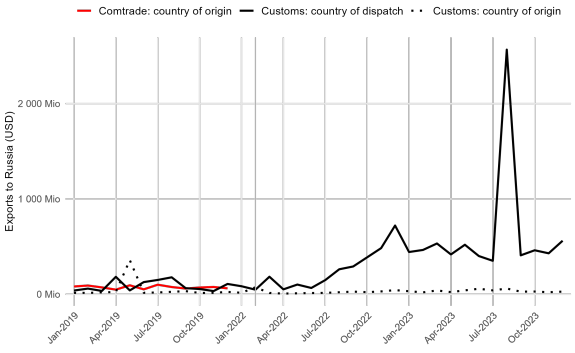

(A) Brazil

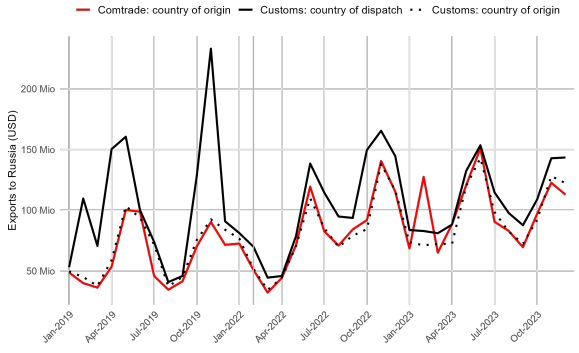

(B) Vietnam

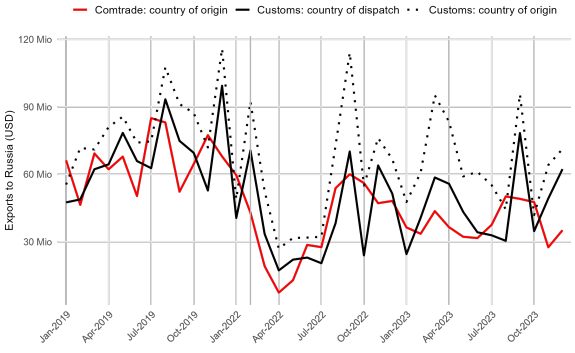

(C) Ecuador

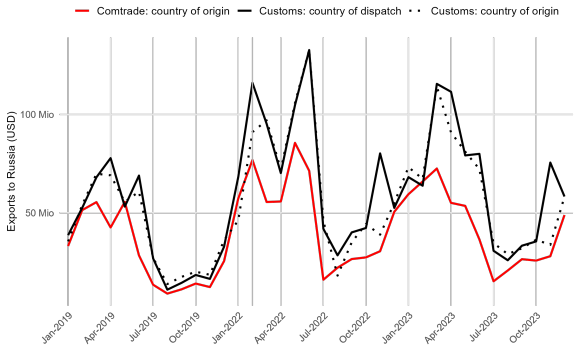

(D) United Arab Emirates

(E) Azerbaijan

(F) Chile

(G) Egypt

Note: The figure shows Russian imports from the customs data (by month, year, and country of dispatch & origin) alongside exports to Russia from the same countries reported in UN Comtrade. Data are shown for 2019 (pre-period) and 2022–2023 (post-onset of the Russian war) for other non-EU, non-coalition exporters with available Comtrade data. Trade values are in millions of US dollars.

Figure C.2. Comparison of UN Comtrade and Russian Customs Data (Other Examples)

C.2 Systematic Comparison with Mirror Statistics

The comparison above covers a few partners. To assess the customs data systematically, we compare them with partner-reported exports for all partners and sectors, taking into account that mirror statistics are noisy for all countries. Let j index exporters, i importers, s sectors, and t years. We use the years 2019, as a pre-war benchmark, and 2022–2024.

Mirror discrepancy For any exporter, importer, sector, and year, we measure the disagreement between exporter-reported exports X^C_{jist} and importer-reported imports M^C_{jist} in UN Comtrade by the symmetric discrepancy

$$D^C_{jist} = \frac{\left|X^C_{jist} - M^C_{jist}\right|}{X^C_{jist} + M^C_{jist}}, \tag{33}$$

which lies between zero (both reports coincide) and one (only one side reports the flow). Cells in which both sides report zero are excluded.

Reliability of mirror reporters A bilateral discrepancy cannot be attributed to either reporter. We therefore decompose the discrepancies in the global Comtrade network into an exporter-sector and an importer-sector component,

$$D^C_{jist} = \alpha^X_{js} + \alpha^M_{is} + \varepsilon_{jist}, \tag{34}$$

which we estimate by non-negative least squares, weighting each observation by the average reported trade value, $w_{jist} = (X^C_{jist} + M^C_{jist})/2$, so that small flows with large proportional discrepancies do not dominate. The reliability of exporter j in sector s is $R^X_{js} = 1 - \hat{\alpha}^X_{js}$. Low reliability need not indicate false reporting; it can also reflect classification and valuation differences, reporting gaps, or sparse observations. We estimate the reliability scores on the 2019 cross-section only and hold them fixed across years, so that the yardstick against which Russia is judged does not absorb post-2022 changes in reporting behavior, including changes related to Russia's own conduct as an importer.[69]

Russia discrepancy For Russia, we replace the importer report with the customs data. The discrepancy D^{RUS}_{jst} is defined as in equation (33), with $X^C_{j,RUS,s,t}$ the exports to Russia reported by partner j in Comtrade and M^{RUS}_{jst} the imports from j recorded in the Russian customs data. Three choices define the Russia object:

[69] Estimating the reliability scores on the pooled sample of all years leaves the results essentially unchanged; the level of the reliability-weighted Russia discrepancy changes by about 0.01 in each year

- *Dispatch basis* We aggregate Russian imports by country of dispatch rather than country of origin. A country that re-exports goods to Russia becomes the seller of record and should report the export in Comtrade, which includes re-exports in its export flows. Matching on the country of origin would instead compare Russian imports of, e.g., EU-origin goods dispatched from a hub with EU-reported exports to Russia, which are zero for banned goods. Dispatch-based discrepancies are lower than origin-based ones in every year, including 2019 (0.23 versus 0.34), so the difference is a structural feature of how the two countries are recorded rather than a consequence of the war.

- *Coalition exclusion* We exclude coalition countries as partners. After the export bans, coalition countries no longer report exports of banned goods to Russia, while Russian customs may still record the corresponding imports, which pushes these cells to the maximum discrepancy by construction.

- *Sector level* We compute the discrepancy at the level of 21 sectors. Discrepancies computed at the HS6 level are roughly twice as high in every year (0.56 versus 0.31 in 2019), reflecting classification differences within sectors.

We aggregate across partners and sectors, weighting each cell by the reliability of the mirror reporter and by trade size:

$$\overline{D}_t^{RUS,w} = \frac{\sum_{j \notin \mathcal{C},\, s} R_{js}^X \, \omega_{jst} \, D_{jst}^{RUS}}{\sum_{j \notin \mathcal{C},\, s} R_{js}^X \, \omega_{jst}}, \qquad \omega_{jst} = \frac{X_{j,RUS,s,t}^C + M_{jst}^{RUS}}{2}, \tag{35}$$

where $\mathcal{C}$ denotes the coalition. Reliability weighting matters: in the baseline comparison by country of origin, the unweighted discrepancy lies between 0.65 and 0.74, whereas the reliability-weighted discrepancy lies between 0.23 and 0.31. A large part of the raw mismatch thus stems from mirror reporters that are themselves unreliable in the global Comtrade network. Reliability scores are missing for 3.2% of the Russian exporter-sector cells.

Benchmark importers For other importers i, we compute the same reliability-weighted discrepancy from Comtrade exports and Comtrade imports, and express it as importer reliability, $R_{it} = 1 - \overline{D}_{it}^{w}$. For Russia, the importer report is taken from the customs data. We benchmark Russia against eleven major economies and against the ten least reliable and the ten highest-discrepancy OECD importers.

Results Averaged over 2019 and 2022–2024, Russia's reliability-weighted discrepancy (0.211) is the second highest among the major economies, below China (0.290) and above India (0.204), Türkiye (0.202), and the large EU economies, the United Kingdom, Japan,

Korea, Brazil, and the United States (0.100–0.179). Russia's position relative to the least reliable OECD importers varies strongly over time. In 2019, its discrepancy (0.275) is the third highest in this group, behind Iceland and Norway, and its importer reliability (0.469) is the lowest. In 2022 and 2023, Russia's discrepancy (0.171 and 0.152) is the lowest in the group, and in 2023 its importer reliability (0.737) is the highest. In 2024, Russia ranks ninth of eleven by discrepancy (0.244). Russia's customs data are thus noisier than the import records of most large economies, but their discrepancy lies within the range of the least reliable OECD importers and does not increase after 2022.

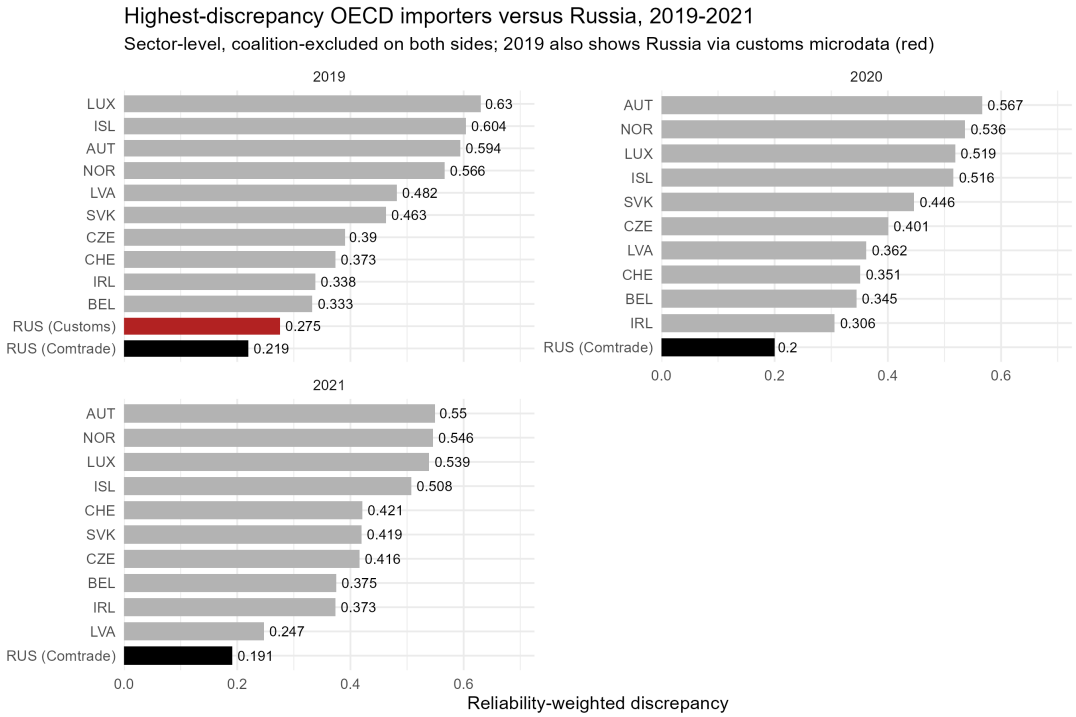

Figure C.3. Mirror Discrepancy before the War: Russia versus the Highest-Discrepancy OECD Importers

Note: The figure shows the reliability-weighted mirror discrepancy of the ten highest-discrepancy OECD importers and Russia, 2019–2021, computed at the sector level with coalition countries excluded as exporters. For Russia, "RUS (Comtrade)" is based on Russia's own import reports to UN Comtrade and "RUS (Customs)" (2019 only, in red) on the Russian customs data. Higher values indicate larger discrepancies between importer-reported imports and partner-reported exports.

Pre-war benchmark Before the war, Russia reported its imports to Comtrade, which allows us to compare the customs data with Russia's own official import statistics. Figure C.3 shows the reliability-weighted discrepancy of the ten highest-discrepancy OECD importers in 2019–2021 together with Russia's discrepancy based on its Comtrade reports and, for 2019, based on the customs data. On its Comtrade reports, Russia's discrepancy (0.219 in 2019, 0.200 in 2020, and 0.191 in 2021) is below that of every OECD importer in the group in all three years (0.333–0.630 in 2019, 0.306–0.567 in 2020, and 0.247–0.550 in 2021). In 2019, the customs-based discrepancy (0.275) is higher than

the Comtrade-based one, but still below the lowest discrepancy in the group (Belgium, 0.333). The customs data are thus somewhat less consistent with partner reports than Russia's official import statistics, but before the war both place Russia below the highest-discrepancy OECD importers.

C.3 Does Russian Reporting Deteriorate in Sanctioned Products?

Our measures of evasion rely on Russian imports of banned products. A deterioration of the customs data concentrated in these products would therefore be a concern. This section first documents that Russia's reporting gap is correlated with sectors' exposure to sanctions and then examines, in four checks, whether this gap has widened specifically in sanctioned products since the invasion.

Fixed-effects model The reliability-weighted comparisons in Section C.2 judge Russia against a pre-estimated yardstick, so Russia's position can shift with the composition of its trading partners. We therefore estimate the importer, exporter, and pair components jointly on the full panel of mirror discrepancies:

$$D_{ijst} = \mu_{ist} + \mu_{jst} + \mu_{ijs} + \varepsilon_{ijst}, \tag{36}$$

where D_{ijst} is the Russia discrepancy for i = Russia and the Comtrade mirror discrepancy otherwise. The exporter-sector-time effect μ_{jst} absorbs the reporting quality of each exporter, and the pair-sector effect μ_{ijs} absorbs time-invariant bilateral differences, so that the importer-sector-time effect μ_{ist} measures the importer's reporting gap net of the composition of its partners. Identification requires that importers trade with changing sets of exporters within sectors. The importer effects are not bounded like the reliability scores and their level depends on the normalization, so only differences in μ_{ist} across importers and years are informative; a higher value indicates a larger discrepancy. Russia's trade-weighted average $\hat{\mu}_{ist}$ lies above the OECD average in every year, and the difference widens from about 0.05 in 2019 to about 0.10 in 2024.

Correlation with sanctions exposure Across sectors, Russia's average $\hat{\mu}_{ist}$ is positively correlated with the share of the sector's HS6 products that are subject to EU export bans (full or partial, as of December 2024): the correlation is 0.66 across the 21 sectors ($t = 3.83$). It remains at 0.66 after excluding arms and ammunition and art and antiques, and at 0.63 after additionally excluding precious metals. This cross-sectional correlation could indicate that Russian reporting deteriorated specifically in the product categories most exposed to sanctions. The following four checks test this interpretation.

Check 1: Bilateral time-varying shocks The importer-sector-time effect could partly reflect shocks to individual bilateral relationships, for instance a single exporter changing how it reports its trade with Russia. We therefore add an importer-exporter-time effect μ_{ijt} to equation (36), which absorbs any shock common to all sectors of a pair in a given year. Russia's trade-weighted $\hat{\mu}_{ist}$ lies within the range of OECD importers in 2019 and rises above the maximum of this range from 2022 onward, while the OECD range remains stable. This rise is broad-based: it occurs in most sectors, including sectors with few or no sanctioned products, such as vegetable products, fats and oils, and food, beverages and tobacco. The post-2022 gap is therefore neither driven by a few bilateral relationships nor confined to sanctioned sectors.

Check 2: Comparison with the most reliable importers If the correlation between sanctioned share and reporting gap reflected a Russia-specific deterioration, it should be absent for other importers and should strengthen for Russia after 2022. Neither is the case. The two most reliable importers in our sample, Italy within the OECD and Romania outside it, show a positive correlation of similar size both in 2019 and in 2022–2023 (Italy: 0.42 and 0.51; Romania: 0.40 and 0.39), although their trade in these products was not affected by the sanctions. Russia's own correlation falls from 0.69 in 2019 to 0.32 in 2022–2023. The correlation thus reflects a general feature of how these product categories are measured in trade statistics.

Check 3: Event study We test directly whether Russia's discrepancy scales more strongly with the sanctioned share after the invasion:

$$D_{ijst} = \sum_{t \neq 2019} \beta_t \left(\text{Russia}_i \times \text{ShareSanctioned}_s \times \mathbb{1}[\text{year} = t]\right) + \mu_{ijs} + \mu_{it} + \mu_{jst} + \varepsilon_{ijst}, \quad (37)$$

where ShareSanctioned_s is the share of HS6 products in sector s subject to EU export bans. The importer-time effect μ_{it} absorbs Russia's overall level shift, and the exporter-sector-time effect μ_{jst} absorbs sanctioned-sector trends common to all importers, so that β_t captures the change, relative to 2019, in how strongly Russia's discrepancy scales with sanctions exposure. Standard errors are clustered by importer. We estimate equation (37) for three samples of comparison importers (all importers, non-coalition importers, and importers whose average discrepancy is at least as high as Russia's) and three weighting schemes (unweighted, weighted by 2019 exporter-sector trade, and weighted by 2019 importer-sector trade). Figure C.4 shows that the sign of $\hat{\beta}_t$ depends on the weighting scheme. The unweighted and importer-sector-weighted estimates indicate a narrowing of the sanctioned-share gradient after 2022, and only the exporter-sector-weighted estimates indicate a widening. The pattern is unchanged when excluding arms and ammunition and

art and antiques. Moreover, with two-way clustering by importer and sector at the 99% level, the exporter-sector-weighted estimates for the comparison group of importers as unreliable as Russia are insignificant in every post-invasion year.

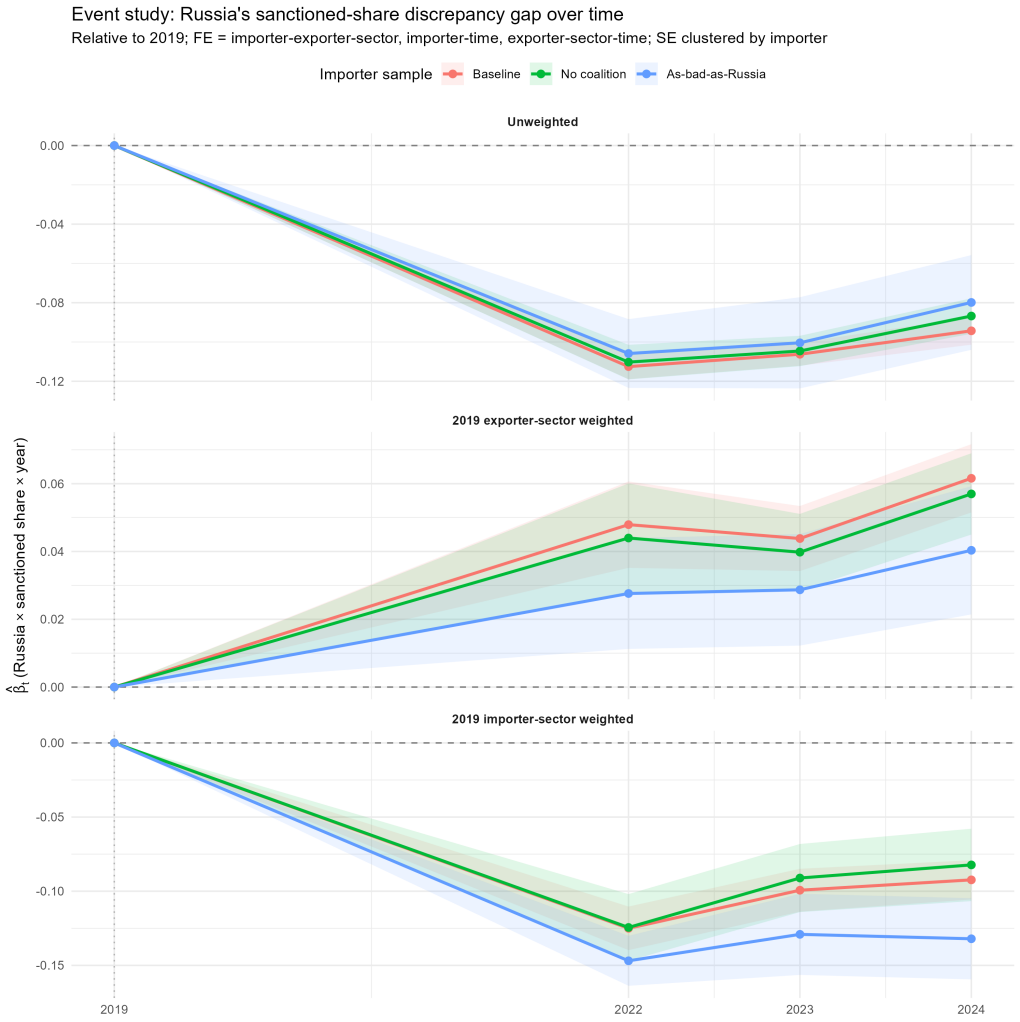

Figure C.4. Event Study: Russia's Sanctioned-Share Discrepancy Gradient over Time

Note: The figure shows the estimated coefficients $\hat{\beta}_t$ from equation (37), relative to 2019, with 95% confidence intervals. Panels correspond to the three weighting schemes, and colors to the three samples of comparison importers. Fixed effects: importer-exporter-sector, importer-time, and exporter-sector-time. Standard errors are clustered by importer.

Check 4: Sanctioned and non-sanctioned products within sectors The most direct test splits each sector into its sanctioned and non-sanctioned HS6 products and compares their discrepancies over time (Figure C.5). Among the ten sectors with the highest sanctioned share, where a differential deterioration should be most visible, nine show no widening of the gap between the sanctioned and the non-sanctioned discrepancy between 2019 and 2024. In several of them (transport equipment, footwear and headgear, paper, and machinery and electrical equipment), the gap narrows or the discrepancy

of non-sanctioned products rises more. The exception, precious metals, rests on only seven non-sanctioned exporter-sector cells. Across all sectors, only arms and ammunition and art and antiques show a rise specific to sanctioned products. Both may reflect the reclassification of exports into special and confidential codes in Comtrade (chapters 98 and 99) and the removal of arms-related codes from published Russian customs statistics, rather than a general deterioration of reporting in sanctioned products.[70]

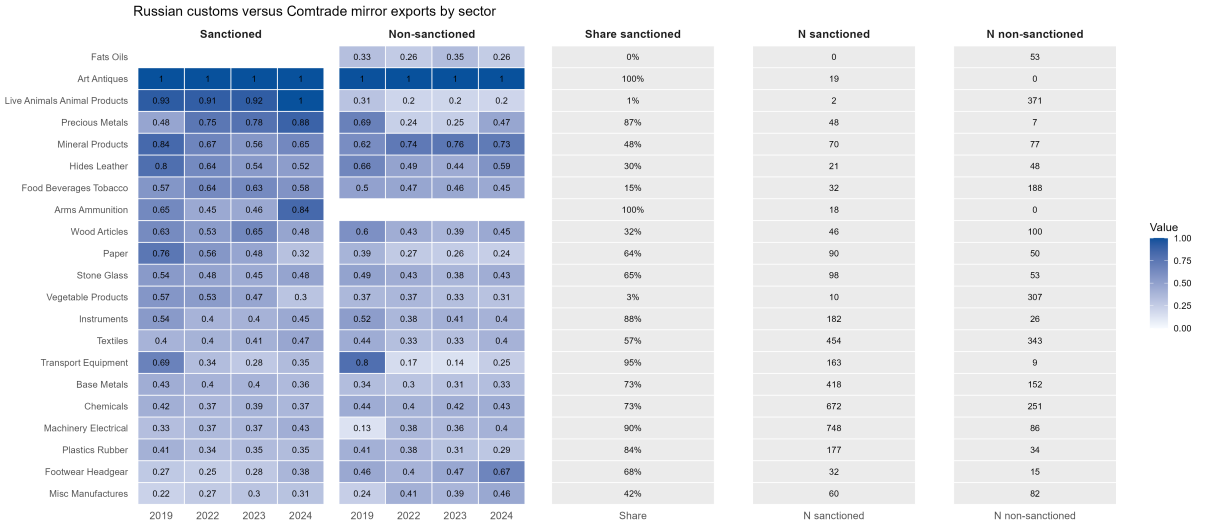

Figure C.5. Discrepancy between Russian Customs Data and Mirror Exports, Sanctioned and Non-Sanctioned Products

Note: The figure shows the reliability-weighted discrepancy between Russian customs imports and partner-reported UN Comtrade exports by sector and year, separately for HS6 products subject to EU export bans (full or partial, as of December 2024) and for all other HS6 products. The right-hand columns report each sector's share of sanctioned HS6 products and the number of sanctioned and non-sanctioned HS6 products. Darker cells indicate larger discrepancies.

Conclusion The four checks, robustness to bilateral time-varying shocks (Check 1), the comparison with the most reliable non-Russian reporters (Check 2), the sensitivity and statistical fragility of the event-study estimates (Check 3), and the direct comparison of sanctioned and non-sanctioned products within sectors (Check 4), converge on the same conclusion. While the cross-sectional correlation between sanctioned-product share and Russia's reporting gap is present, we find no robust evidence that this gap has grown differentially wider in sanctioned sectors relative to non-sanctioned sectors, or relative to other importers, since the invasion. The evidence thus rules out that misreporting of import flows by Russian customs is concentrating and intensifying specifically in the product categories most exposed to sanctions.

[70] The Russian customs data contain no codes in HS chapters 77, 98, or 99, no product codes at a coarser level than the regular tariff lines, and no non-numeric codes. If exporters report confidential shipments under chapters 98 or 99 in Comtrade, the corresponding Russian imports therefore appear under their regular product codes, which raises the measured discrepancy in the respective sector without any inconsistency in the customs data. We cannot identify which customs records are affected.

D Dictionary for Classifying Trading Firms

We classify a sender as a trading firm if its name contains at least one of the 29 terms in Table D.1, matched as whole words. Because names without any listed term remain unflagged, the resulting shares are lower bounds on the role of trading firms.

Table D.1. Dictionary Terms for Trading Firms

Language	Terms
English	trading, trade, traders, general trading, international trade, commerce, commercial, mercantile, import (and) export, imp (and) exp, impex
Turkish	*ticaret* (trade), *dış ticaret* (foreign trade), *ihracat* (export), *ithalat* (import), *pazarlama* (marketing)
Russian	*eksport* (export), *import* (import), *torgovyi dom* (trading house), VED (foreign economic activity)
Other	*Handel, Handels* (trade, DE/PL); *comercio, comercial* (ES/PT); *commercio* (IT); *exportação, importação* (PT)
Example	`VDV DIS TICARET LIMITED SIRKETI`

E Details on the Calibration

This appendix provides the details of the calibration summarized in Section 4.3.

Table E.1. Model Parameters

Parameter	Value	Source or Target
Trade elasticities, θ^k	1.5 to 44.1 (median 8.2)	Fontagné et al. (2022)
Within-group elasticity, σ_g	2.2	French (2016)
Cross-group elasticity, ν	1.1	Assumption
Lower bound on home shares	10%	Assumption
Baseline trade costs, τ^k_{ei}	By product and country pair	Gravity inversion, triangle inequalities
Relative hub wedges, $\widetilde{\rho}_h$	By hub	Hub shares, Russian customs data
Common level of the wedges, a	1.34	Estimated effect of the full bans
Partial-ban cost increase, δ_P	1.100 (an increase of 10%)	Estimated effect of the partial bans

Notes. This table reports the parameters of the model, their values in the main specification, and where these values come from.

E.1 Data, Sample, and Elasticities

We calibrate the model at the 6-digit HS level, the most detailed product classification that is harmonized across countries. At this level, we can impose the export bans product by product. In the more aggregated quantifications that are standard in the literature, the bans cannot be mapped cleanly into sectors. Product-specific import shares and trade elasticities also allow the ease of replacing a sanctioned origin to vary across narrowly defined products, and the model's rerouting of each origin and product can be compared directly with the customs data. The cost of this disaggregation is that expenditure is not observed at the product level, so we recover it from the structure of the model, as explained below.

Trade and absorption data. We use data from 2019, the last full year before COVID and the war. Bilateral product-level trade flows from UN Comtrade measure X^k_{ei} for $e \neq i$, with products defined at the HS6 level in the HS2017 vintage. For each reporting side, we first aggregate records that are split by customs procedure, transport mode, and second partner country. To limit the effect of missing or incomplete mirror reports, we then use the larger of the importer's reported imports and the exporter's reported exports.

To measure total expenditure, X_i, and the domestic expenditure underlying X^g_i, we use the OECD Inter-Country Input-Output tables (regular ICIO, 2025 edition). For each of the ICIO's goods industries, expenditure on domestically produced goods equals gross output minus exports (set to zero where recorded exports exceed recorded output), and total expenditure adds imports to this amount. For countries missing from ICIO, we use

the International Trade and Production Database for Estimation (ITPD-E, Release 2; see Borchert et al. (2021)).[71]

To keep the quantification tractable at the HS6 level, we restrict the sample to the countries in the UN Comtrade data that (i) implement export bans against Russia,[72] (ii) are among Russia's top 50 import origins or top 50 export destinations in 2019, (iii) are members of the Eurasian Economic Union, or (iv) dispatched at least 0.5% of the value of the fully banned goods of the EU and the countries mirroring its sanctions that Russia imported through countries outside the coalition in 2024. This leaves 74 countries, which account for 96% (98%) of Russia's total exports (imports) and 93% (92%) of world exports (imports).[73] Finally, we drop HS6 products for which Russia's total 2019 trade is less than USD 10,000 on both the import and the export side. A further 11 products trade in too few markets for the regression below to estimate their product-level effects, leaving 5,136 products in the final sample.[74]

Elasticities. As is common in the literature, we do not estimate the elasticities ourselves. We take the trade elasticities, θ^k, from Fontagné et al. (2022), who estimate product-level trade elasticities using gravity regressions consistent with our setup. For 6-digit products that cannot be matched to their data, we use the average elasticity within the product's 4-digit heading. Because the estimates contain some outliers, we winsorize them at the 1st and 99th percentiles. We assign the median of the matched elasticities to the 85 products without a match at either level. The resulting trade elasticities range from 1.5 to 44.1,

[71] The ITPD-E data sometimes imply very small (or even negative) expenditure on domestically produced goods. We therefore use these data only for countries for which ITPD-E reports positive domestic expenditure in at least 50 of its 153 goods industries, which are more disaggregated than the ICIO industries, and these industries cover at least 40% of the country's recorded imports. For the other countries missing from ICIO, we use as a reference group the ICIO countries whose population lies on the same side of the sample median, which allows home-expenditure shares to differ with country size. We choose a country's total domestic expenditure such that, given its imports, its home-expenditure share (expenditure on domestically produced goods divided by the sum of this expenditure and imports) equals the unweighted average across the reference group. We then distribute this total across industries according to the pooled domestic expenditure of the reference group.

[72] For Taiwan, we use its own reports to UN Comtrade (reporter code 490), because its partners record their trade with Taiwan only under the residual category "Other Asia, not elsewhere specified," which may also contain other flows.

[73] We treat China and Hong Kong as a single country when calibrating the model (reassigning Hong Kong's flows to China) due to large shares of re-exports between these countries, as is frequently done in the quantitative trade literature. We treat Liechtenstein and Switzerland in the same way, as Liechtenstein has no separate customs territory and no separate presence in UN Comtrade. In both cases, we combine the two territories' flows on each reporting side before taking the maximum across sides. We do not aggregate the remaining countries into a rest-of-the-world region.

[74] These are the products for which the regression yields no importer-product effect or no exporter-product effect for any country.

with a median of 8.2. Russia can therefore replace a sanctioned supplier much more easily for some products than for others.[75]

Within groups, we set $\sigma_g = 2.2$ for all three groups, in line with French (2016). Across groups, we set $\nu = 1.1$, close to the Cobb–Douglas case and half the within-group elasticity. Russia therefore substitutes much less easily across the three groups than within them. However, Section 5 shows that Russia's real-income losses and its transshipment gain barely change when we lower ν below one, raise it to σ_g, which places all products in a single CES nest, or lower the within-group elasticity of military-relevant goods to $\sigma_M = 1.2$.

E.2 Product Groups and Expenditure

Product groups. We assign the 5,136 products to the three groups based on existing lists of battlefield-relevant and strategic goods. Group M starts from the 44 battlefield-relevant products listed in Table A1 of Scheckenhofer et al. (2025) and, after two adjustments, contains 42 products.[76] Beyond battlefield goods, sanctions target products with high strategic value. The EU's export-control framework identifies these products through two lists. The dual-use list covers goods with both civilian and military uses, and the advanced-technology list (Annex VII) covers goods and technology that might contribute to Russia's military and technological enhancement. Both lists are defined at a more disaggregated level than HS6, and group C contains every HS6 product with at least one tariff line on either list.[77] Net of the products already in M, this yields 967 products, spanning machine tools, electronics, precision instruments, chemicals, and metals.[78] Table A1 predates the February 2024 update of the Common High Priority Items list (version of February 2024),

[75] Every θ^k exceeds $\sigma_g - 1$, with σ_g as set below. This ensures that the exponent used in the expenditure recovery below is positive and that one can choose an η^k satisfying both $\eta^k > \sigma_g$ and $\theta^k > \eta^k - 1$ (see Section 4.1). Because η^k otherwise affects only the product-specific price-index constant that we absorb into T_e^k, it need not be calibrated separately, a standard result in EK-type models.

[76] First, we move the three products of the HS 8517 phone family (851712, 851762, and 851769) to C, because they entered the battlefield list as sources of components rather than as military equipment. Second, we add HS 854150 (other semiconductor devices), because the battlefield list, which uses a later HS version, contains both codes into which 854150 was split.

[77] Accordingly, if one line of an HS6 product is listed, we attribute the full HS6 product to that specific group. By contrast, in Section 2.1, we treat an HS6 product as fully banned only if the bans cover all of the goods within that HS6 category.

[78] The product lines come from the European Commission's correlation tables. For the dual-use list (Regulation 2021/821), we use the table valid through 31 December 2024 (available here; retrieved 4 August 2026), matching our end-2024 sanctions data, while for Annex VII (Regulation 833/2014), the 2026 vintage (available here; retrieved 28 July 2026) is the earliest available to us. The dual-use table lists ten-digit TARIC codes, which we truncate to six digits, and where it lists only a four-digit heading, we include all products of that heading. From the Annex VII table we take every complete eight-digit CN code, whereas rows without one (software and technology items, free text) identify no product line and are dropped. Codes published in later HS vintages are converted to HS2017 with the one-to-one conversion sheet of the official UN conversion table.

which added five machine-tool products (Tier 4.B). These products are covered by the two EU lists and therefore fall into C. The remaining 4,127 products form group O.

Group expenditure, X_i^g, consists of imports and domestic absorption of the group's products. For imports, we simply add up the imports of the products in each group. Domestic absorption, however, is recorded by ICIO industry rather than by product, and we allocate it in two steps. First, we map each HS6 product to one of the ICIO's 26 goods industries (agriculture, mining, and manufacturing) using all rows of the official UN correspondence tables (HS2017 to CPC 2.1 to ISIC Rev. 4), including those flagged as partial. For 95.6% of import value in our sample, these rows single out one industry.[79] Second, we split each industry's domestic absorption across M, C, and O in the same proportions as the country's imports within that industry, since imports are the only expenditure we observe at the product level. If a country has no imports in an industry, we use the industry's import composition summed over all sample countries. Group imports plus allocated domestic absorption then give X_i^g.[80] This allocation assumes that, within an ICIO industry, expenditure on domestically produced goods is split across M, C, and O in the same way as imports. For Russia, the three groups account for 1.6% (M), 30.7% (C), and 67.8% (O) of total expenditure.

Product-level expenditure. We cannot read X_i^k (i.e., product-level expenditure) directly from the data, because expenditure is not observable at this level of disaggregation globally. We therefore recover k-level expenditure (and, accordingly, domestic product-level trade) using the model's structure.[81]

Next, we allocate group expenditure, X_i^g, across the products of each group. By equation (9), this allocation is pinned down by the product-level price indices, P_i^k, which we need to estimate. We cannot simply use equation (11) to estimate P_i^k, because the dependent variable itself is scaled by X_i^k. However, combining equations (9), (11), and

[79] For the remaining 4.4% of import value, the correspondence tables give no industry or several. In these cases, we use the industry that produces the goods of the product's HS2 chapter (for instance, chemicals for chapters 28 and 29). If the tables offer several industries and the chapter's industry is not among them, we choose the industry to which most of the unambiguously mapped products of the same HS4 heading belong. For the products where neither rule decides (HS 310100, 440210, 440290, and 940690), we take the industry that comes first in the ICIO industry code order.

[80] Let D_{ir} denote domestic absorption and I_{ir}^g imports of group g in country i and ICIO industry r. The allocation is

$$D_{ir}^g = \begin{cases} D_{ir}\dfrac{I_{ir}^g}{\sum_s I_{ir}^s}, & \text{if } \sum_s I_{ir}^s > 0, \\ D_{ir}\dfrac{\sum_j I_{jr}^g}{\sum_j \sum_s I_{jr}^s}, & \text{if } \sum_s I_{ir}^s = 0, \end{cases}$$

where s runs over the three groups and j over the sample countries, with $X_i^g = \sum_r \left(D_{ir}^g + I_{ir}^g\right)$.

[81] French (2016) recovers product-level expenditure while assuming that trade costs and trade elasticities are common across products, whereas Torun (2025) uses a non-homothetic final-goods aggregator to do so.

(12), we obtain

$$\frac{X_{ei}^k}{X_{ei}} = \frac{T_e^k w_e^{-\theta^k} \Lambda_i^{g(k)} (P_i^k)^{\theta^k - (\sigma_{g(k)}-1)} (\tau_{ei}^k)^{-\theta^k}}{\sum_{s=1}^K T_e^s w_e^{-\theta^s} \Lambda_i^{g(s)} (P_i^s)^{\theta^s - (\sigma_{g(s)}-1)} (\tau_{ei}^s)^{-\theta^s}},$$

where $X_{ei} := \sum_{s=1}^K X_{ei}^s$ denotes total bilateral trade and the group scale $\Lambda_i^g := X_i^g (P_i^g)^{\sigma_g - 1}$ collects the group-level terms, which are common to all products of group g in country i. Taking logs of this equation yields

$$\log\left(\frac{X_{ei}^k}{X_{ei}}\right) = \log\left(T_e^k w_e^{-\theta^k}\right) + \log\left(\Lambda_i^{g(k)} (P_i^k)^{\theta^k - (\sigma_{g(k)}-1)}\right) - \log\left(\Psi_{ei}\right) - \theta^k \log\left(\tau_{ei}^k\right),$$

where $\Psi_{ei} := \sum_{s=1}^K T_e^s w_e^{-\theta^s} \Lambda_i^{g(s)} (P_i^s)^{\theta^s - (\sigma_{g(s)}-1)} (\tau_{ei}^s)^{-\theta^s}$. We run an OLS regression with $\log\left(X_{ei}^k / X_{ei}\right)$ as the dependent variable on all positive bilateral flows. The first three elements on the right-hand side can be captured by an exporter-product fixed effect (FE), an importer-product FE, and an exporter-importer FE, respectively. To parametrize the impact of τ_{ei}^k, we interact a set of product dummies with several standard bilateral variables: the log of population-weighted distance, as well as dummy variables indicating whether the country pair has a free trade agreement or is part of the same customs union, and whether it shares a common border, language, or colonial history. These control variables are obtained from the standard CEPII Gravity database (Conte et al. 2022).

Therefore, through the lens of the model, the exponentiated importer-product FE yields the composite $B_i^k := \Lambda_i^{g(k)} (P_i^k)^{\theta^k - (\sigma_{g(k)}-1)}$ rather than the price index alone. Because every θ^k exceeds $\sigma_g - 1$, this exponent is positive, so a higher B_i^k corresponds to a higher P_i^k at a given group scale. The regression pins down the exporter-product and importer-product FEs only jointly, so a product-specific constant can be shifted from one set of effects to the other without changing any fitted share. We normalize the estimated B_i^k to a geometric mean of one across importers within each product and absorb the offsetting constant into the exporter-product effects. For importer-product cells where the regression yields no estimate, we set B_i^k equal to the maximum estimate within k (recall that a higher P_i^k implies more difficult access to cheap sources). Moreover, due to outliers in these estimates, we winsorize B_i^k by bounding values below the 10th and above the 90th percentiles within each importer i and group g. Recovering P_i^k from B_i^k then requires the group scales Λ_i^g, which the regression does not pin down. We normalize $\Lambda_i^O = 1$ and solve, country by country, for the two remaining scales such that the implied group expenditures match their measured ratios (with X_i^g measured as described above),

$$\frac{\Lambda_i^g (P_i^g)^{1-\sigma_g}}{(P_i^O)^{1-\sigma_O}} = \frac{X_i^g}{X_i^O}, \qquad g \in \{M, C\},$$

where the group price indices follow from equation (6) and $\Lambda_i^g (P_i^g)^{1-\sigma_g}$ is the group expenditure for a given scale. The left-hand side is strictly increasing in Λ_i^g, so each equation has a unique solution. Equation (9) then yields X_i^k, which adds up to X_i^g within each group, and hence to X_i, by construction. Domestic product-level trade follows as the residual $X_i^k - \sum_{e \neq i} X_{ei}^k$. The elasticity ν plays no role in this step, because group expenditure is already measured at this point, but it governs how expenditure shifts across the three groups in the counterfactuals.

Because product-level expenditure is recovered rather than directly observed, it is sometimes only slightly larger than a country's observed imports of the product, and sometimes even smaller. Expenditure on domestically produced goods, the difference between the two, is then very small or even negative. Since the home share, together with the trade elasticity, is known to be a main determinant of welfare changes in this class of models, such cases may produce extreme results. As a final step, we therefore impose a lower bound of 10% on each product's home share, π_{ii}^k, which initially binds for 15% of all country-product pairs. Where the bound binds, we raise the product's expenditure until its home share reaches 10%, and we scale down expenditure on the other products of the same group proportionally, which leaves group expenditure unchanged. We repeat this until all products satisfy the bound. Imports remain at their observed values throughout. In 19 of the 74 countries, the measured expenditure of a group is too small to satisfy the bound for all of its products. In these countries, we raise the group's expenditure share by as little as necessary and scale down the shares of the other groups proportionally, which changes group shares by at most 1.8 pp and leaves total expenditure unchanged. Russia is not among these countries. The resulting domestic and bilateral flows give the baseline trade shares, π_{ei}^k. Section 5 reports results with a lower bound of 5%.

E.3 Baseline Trade Costs

To recover the initial trade barriers, we use the trade shares, π_{ei}^k, and the exporter-product FEs of the regression above, whose exponential yields $T_e^k w_e^{-\theta^k}$. For exporter-product cells where the regression yields no estimate, we set $T_e^k w_e^{-\theta^k}$ equal to the minimum estimate within k (recall that a lower $T_e^k w_e^{-\theta^k}$ implies less export competitiveness), and we winsorize by bounding values below the 10th and above the 90th percentiles within each exporter e across all products. The winsorization of B_i^k is done within group instead, because B_i^k contains the group scale Λ_i^g, whose level differs across groups. According to the gravity equation, trade barriers can be backed out using bilateral relative to domestic flows,

$$\tau_{ei}^k = \left(\frac{\pi_{ei}^k / (T_e^k w_e^{-\theta^k})}{\pi_{ii}^k / (T_i^k w_i^{-\theta^k})} \right)^{-1/\theta^k}, \tag{38}$$

which matches the positive baseline trade flows exactly, in line with the hat-algebra logic.[82]

We then need to ensure that the initial trade costs satisfy the TIs to have a theory-consistent starting point. The gravity-implied barriers from equation (38) need not satisfy the triangle inequalities, because the bilateral term recovered from gravity combines route-related trade costs with other pair-specific barriers, such as bilateral preference shifters (Foellmi et al. 2024). To recover trade costs, we apply the algorithm from Foellmi et al. (2024, Section 4) and update the τ_{ei}^k values from equation (38) iteratively until we have no more TI violations. This yields a set of TI-consistent trade costs, which we then use to measure transshipment opportunities following a shock.[83]

E.4 Hub Shares and Hub Wedges

Multiplying all wedges by the same factor makes every hub route more costly but does not change which one is the cheapest. The observed hub shares thus identify the wedges only up to a common scale, and we write them as

$$\rho_h = a\,\widetilde{\rho}_h, \tag{39}$$

where a is their common level and the relative wedges, $\widetilde{\rho}_h$, have a geometric mean of one across potential hubs.

Hub shares. For each potential hub, we count the fully banned origin-product cells of the EU and the mirroring countries for which at least USD 1,000 of imports reached Russia through this hub between May and December 2024. A hub's share is this count divided by the total across hubs.[84] Since the customs data report the point of entry (Section 4.3) mostly from May 2024 onward, we use the months from May to December 2024 for all shipments. In the data, Belarus serves as a hub for some products whose exports to Belarus are banned. Since the model cannot route these products through Belarus, it can match Belarus's share only through its other products.

[82] For zero bilateral trade shares, we replace the relative share term in parentheses by 10^{-12}, which implies a gravity barrier of $\tau_{ei}^k = 10^{12/\theta^k}$ before the TI adjustment described next.

[83] The algorithm starts by setting the trade barriers that we obtain from equation (38) to at least one. Then, it verifies the TIs, and if a TI is violated, it sets the updated trade cost equal to the minimum indirect cost. This procedure is repeated until there are no more TI violations. The wedge between the initial value of trade barriers and the final value of trade costs can be interpreted as a bilateral preference shifter through the lens of standard gravity theory (cf. Foellmi et al. 2024). Because exact hat algebra conditions on the observed baseline trade shares, this residual need not be recovered separately. The levels τ_{ei}^k are needed only to determine rerouting opportunities and the corresponding trade-cost changes.

[84] Counting a hub when it accounts for at least 1% of the imports of an origin-product cell, instead of at least USD 1,000, yields nearly the same shares, with a correlation of 0.999.

Relative wedges. We then choose the relative wedges such that the model's hub shares match the observed ones as closely as possible. Specifically, the relative wedges minimize $\sum_h (s_h - s_h^{\text{data}})^2 + \lambda \sum_h (\log \widetilde{\rho}_h)^2$, where s_h and s_h^{data} denote hub h's share in the model and in the data, respectively. The penalty term, with the small weight $\lambda = 10^{-4}$, keeps the wedges of countries that rarely serve as hubs close to the common level, since their shares carry little information about their wedges.

Common level. By the gravity equation (11), the direct effect of a full ban equals $(m^k_{(1),eR}/\tau^k_{eR})^{-\theta^k}$ for Russia's imports of product k from origin e. We choose a such that

$$\frac{\sum_{(e,k)\in\mathcal{F}} X^k_{eR}\left(m^k_{(1),eR}/\tau^k_{eR}\right)^{-\theta^k}}{\sum_{(e,k)\in\mathcal{F}} X^k_{eR}} = \exp\left(\hat{\beta}_F\right), \tag{40}$$

where $\hat{\beta}_F$ is our estimate of the effect of full bans in Section 3.1 and $\mathcal{F}$ is the set of origin-product cells of the EU and the mirroring countries that are fully banned at the end of 2024 and have positive exports to Russia in 2019.[85] This yields $a = 1.34$, so rerouting through a hub with a relative wedge of one costs 1.34 times as much as in the model without hub wedges.

Partial-ban cost increase. We calibrate δ_P to the estimated effect of the partial bans, holding the hub wedges at their calibrated values. To estimate this effect, we rerun the triple-DiD specification in equation (2) with products that remain partially banned through December 2024 as the treated group, so that later upgrades to full bans do not contaminate the estimate. Figure E.1 shows the resulting event study. Relative to never-sanctioned products, imports of partially banned EU products fall by 47% on average after the bans. We then choose δ_P such that the model's average direct effect of the partial bans equals this estimate. The average is taken over the partially banned origin-product cells of the EU and the mirroring countries with positive exports to Russia in 2019, weighted by their 2019 values. For each cell, the direct effect uses the cost in equation (17), the lower of δ_P times the pre-war direct cost and the cost of the cheapest hub route. The result is $\delta_P = 1.100$.

E.5 Untargeted Fit

The relative wedges target only the aggregate hub shares of the EU and the countries that mirror its sanctions. The routing of the other coalition origins, the distribution of hubs within individual origins, the value-weighted hub shares, and the variation across product

[85] Since $\rho_h = a\widetilde{\rho}_h$ cannot fall below one, no relative wedge can be lower than $1/a$. The relative wedges that best match the hub shares can therefore depend on a, and we calibrate the two jointly.

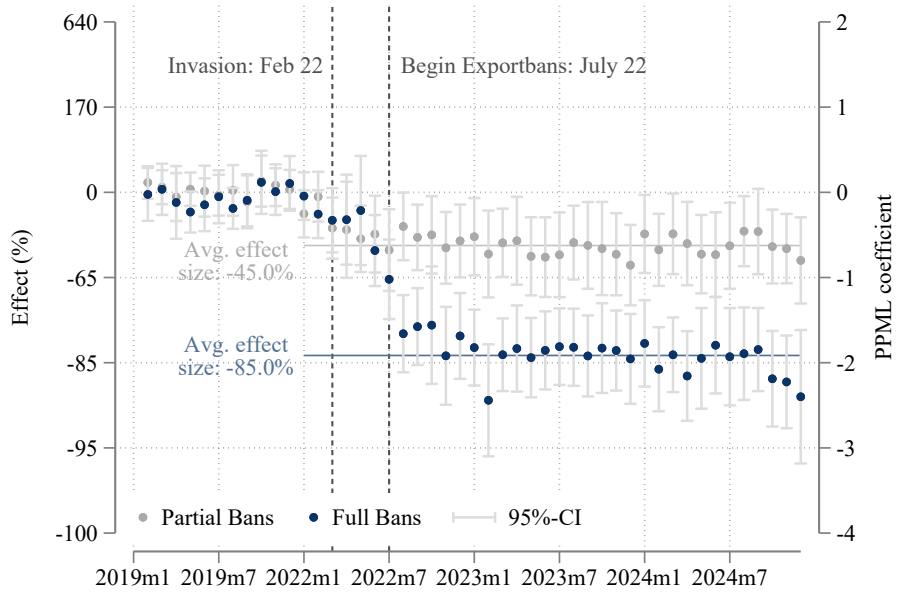

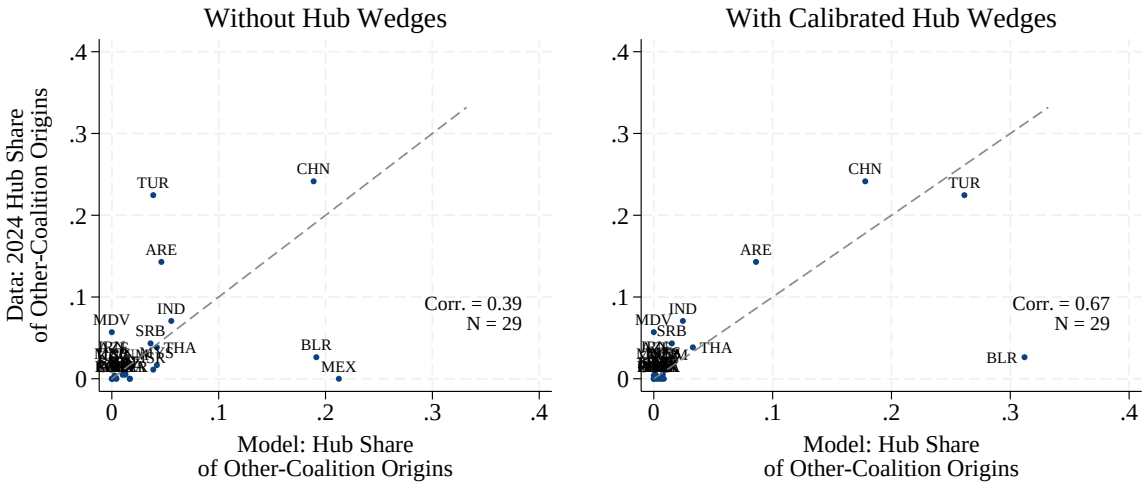

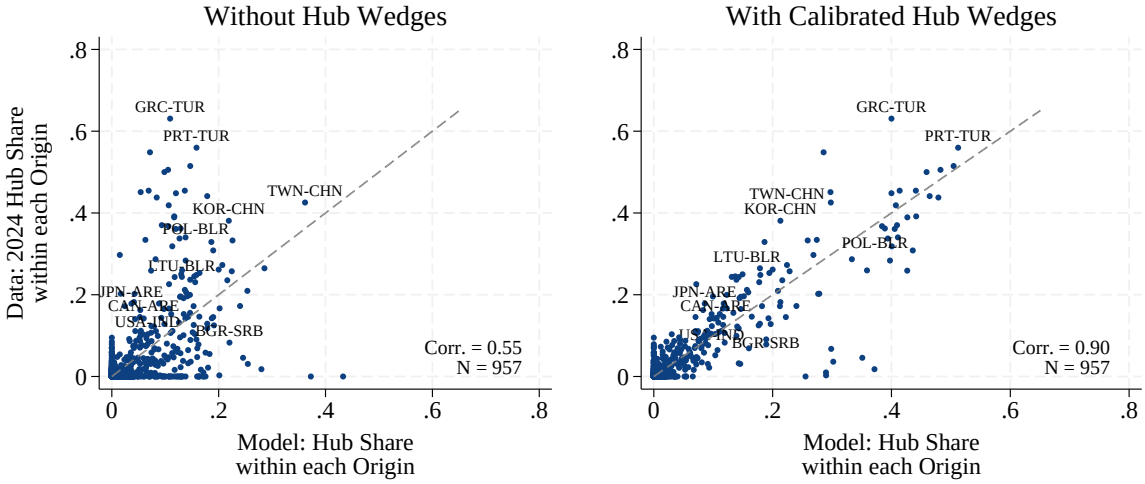

Figure E.1. Event Study: Partial Export Bans and Russian Imports

Notes: The figure plots monthly PPML coefficients $\hat{\beta}_m^P$ of equation (2) for Russian imports of products that remain partially banned through December 2024, with never-sanctioned products as controls. Coefficients are relative to January 2019 (right axis); the left axis shows implied trade-flow changes, $(e^{\hat{\beta}_m^P} - 1) \times 100\%$. The horizontal line marks the average post-ban effect. Bars show 95% confidence intervals clustered by product and origin; vertical lines mark the invasion (February 2022) and the export bans (July 2022).

sectors are therefore untargeted. For the remaining coalition origins, the correlation between the model's and the observed hub shares rises from 0.39 in the model without hub wedges to 0.67 with the calibrated wedges (Figure E.2a). For hub shares computed within each coalition origin, the correlation across origin-hub pairs rises from 0.55 to 0.90 (Figure E.2b). The fit also improves for value-weighted hub shares and for hub shares within HS2 chapters (Figure E.3). These comparisons use the same 2024 customs data as the calibration target and are therefore untargeted rather than out-of-sample.

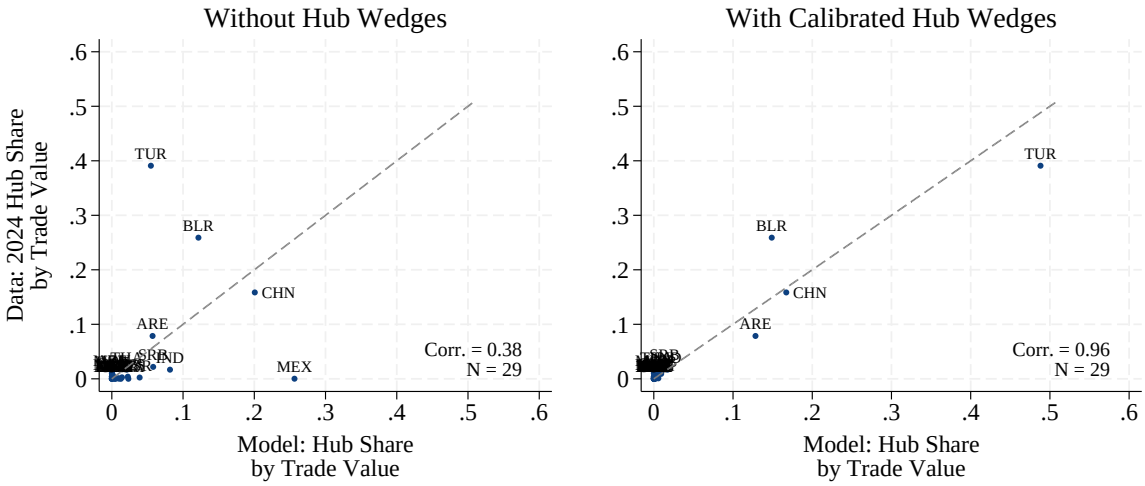

(A) Hub Shares of the Other-Coalition Origins

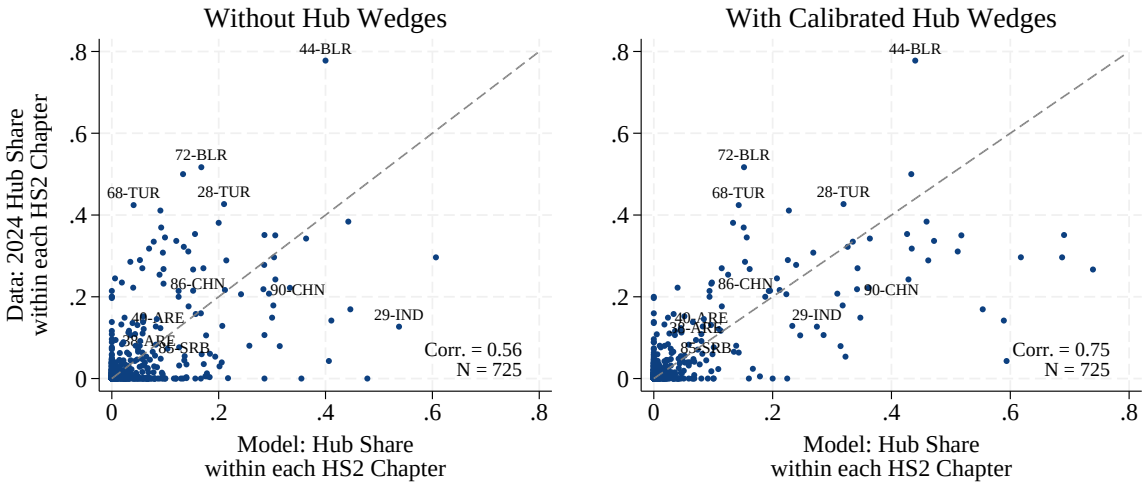

(B) Hub Shares within Each Origin, by Origin-Hub Pair

Figure E.2. Untargeted Fit of the Calibrated Hub Wedges

Note: This figure compares the hub shares of fully banned goods in the Russian customs data for May to December 2024 (vertical axis) with those in the model (horizontal axis), without hub wedges in the left panels and with the calibrated wedges in the right panels. Panel E.2a shows the hub shares of the coalition origins outside the EU and the mirroring countries. Panel E.2b shows the hub shares within each coalition origin, for the 33 origins with at least 25 origin-product cells that are rerouted in both the model and the data. Labels identify ten origin-hub pairs with high shares. The dashed line is the 45°-line. "Corr." is the correlation across the plotted points, and "N" is the number of points.

(A) Hub Shares by Trade Value, All Coalition Origins

(B) Hub Shares within Each HS2 Chapter, by Chapter-Hub Pair

Figure E.3. Untargeted Fit of the Calibrated Hub Wedges: Values and Chapters

Note: Like Figure E.2, this figure compares the hub shares of fully banned goods in the Russian customs data for May to December 2024 (vertical axis) with those in the model (horizontal axis), without hub wedges in the left panels and with the calibrated wedges in the right panels. Panel E.3a shows the hub shares of all coalition origins measured by trade value. Panel E.3b shows the hub shares of all coalition origins within each HS2 chapter, measured as in Figure E.2, for the 25 chapters with at least 25 origin-product cells that are rerouted in both the model and the data. Labels identify ten chapter-hub pairs with high shares, with each chapter given by its two-digit HS code. The dashed line is the 45°-line. "Corr." is the correlation across the plotted points, and "N" is the number of points.

F Modeling Hub Rents

In the thought experiment of Section 5, potential hubs compete to provide the intermediation service. Let $m^k_{(1),eR}$ denote the lowest route cost across the countries that can serve as intermediaries, with route costs as in equation (15), and let $m^k_{(2),eR}$ denote the cost of the cheapest competing route. The country with the lowest route cost is selected, while the competing route limits the markup that it can charge without losing the trade flow. This introduces a Bertrand-like pricing structure.[86] The gross markup charged by the selected hub is

$$\kappa^k_{eR} = 1 + \min\left\{\frac{m^k_{(2),eR}}{m^k_{(1),eR}} - 1,\ \frac{1}{\theta^k}\right\}. \tag{41}$$

The first term inside the minimum limits the markup by the cost of the competing route. For a fully banned flow, this is the second-cheapest hub route, and we set $m^k_{(2),eR} = \infty$ if only one country can serve as an intermediary for this flow. For a partially banned flow, the direct route also competes with the selected hub, so $m^k_{(2),eR}$ is the lower of the second-cheapest hub route cost and the direct cost $\delta_P \tau^k_{eR}$. The second term is the markup that maximizes the hub's revenue. Where the competing route would allow a higher markup, the hub still charges this one, because a higher markup would reduce Russian demand for the rerouted flow so much that its revenue falls.[87]

The trade cost of a rerouted flow is $m^k_{(1),eR}\kappa^k_{eR}$. Let $X^{k\prime}_{ei}$ denote importer i's gross expenditure on product k from origin e in the counterfactual equilibrium. For a flow that is not rerouted, $\kappa^k_{ei} = 1$, and the exporter receives the full amount. For a rerouted flow, the original exporter receives $X^{k\prime}_{eR}/\kappa^k_{eR}$, while the selected hub receives $\left(1 - 1/\kappa^k_{eR}\right) X^{k\prime}_{eR}$. We treat the markup as pure rent, so it reallocates income between the exporter and the hub rather than using additional resources. By contrast, the wedge ρ_h is an iceberg cost of rerouting and generates no rents for the hub. Let $h^\star(e,k)$ denote the hub selected for exports of product k from origin e to Russia. The rents of hub country h are

$$R'_h = \sum_{e,k:\, h^\star(e,k)=h} \left(1 - \frac{1}{\kappa^k_{eR}}\right) X^{k\prime}_{eR}. \tag{42}$$

We assume that this income is rebated to the representative household of the hub country. For intuition, note that the rents are analogous to tariff revenue in a standard quantitative

[86] This follows the Bertrand-pricing logic in Bernard et al. (2003), where the lowest-cost supplier serves the market, while the cost of the second-best supplier constrains the price it can charge.

[87] To derive this markup, hold Russian expenditure on product k, wages, and competing origins' trade costs fixed, and let the hub take the Russian product price index as given. From the gravity equation (11), multiplying its trade cost by κ then implies that gross bilateral expenditure satisfies $X^k_{eR}(\kappa) \propto \kappa^{-\theta^k}$. The hub retains the fraction $1 - 1/\kappa$ of this expenditure, so its revenue is proportional to $(1 - 1/\kappa)\kappa^{-\theta^k}$. The derivative of this expression with respect to κ is $\kappa^{-(\theta^k+2)}\left[(\theta^k+1) - \theta^k\kappa\right]$, which is positive below and negative above $\kappa^\star = 1 + 1/\theta^k$, so revenue is highest at the proportional markup $\kappa^\star - 1 = 1/\theta^k$.

trade model such as Caliendo and Parro (2015). With a gross tariff factor $\kappa = 1 + t$, importer expenditure is split into exporter income $X/(1+t) = X/\kappa$ and tariff revenue $tX/(1+t) = (1 - 1/\kappa)X$. Here, this revenue accrues to the intermediary country rather than to the importing government.

Because labor is the only production input, the wage bill in exporter e equals its sales net of hub markups,

$$w'_e L_e = \sum_{i=1}^{N} \sum_{k=1}^{K} \frac{X_{ei}^{k\prime}}{\kappa_{ei}^{k}}, \tag{43}$$

and total expenditure in country i is labor income plus any rents earned as a hub,

$$X'_i = w'_i L_i + R'_i. \tag{44}$$

In the main specification, $\kappa_{ei}^{k} = 1$ and $R'_i = 0$, so these conditions reduce to equation (18).

With these markups, we recalibrate the hub wedges and the partial-ban cost increase so that the model still matches the observed hubs and the estimated effects of the full and partial bans. Since each hub charges the maximum markup it can, the resulting rents are an upper bound on what the hubs can earn from rerouting.[88] Except for Türkiye, the real wages of the hubs in Table F.1 change by about as much as their real income does in the main specification. For these hubs, the rents therefore come on top of what they gain or lose from the sanctions without markups.

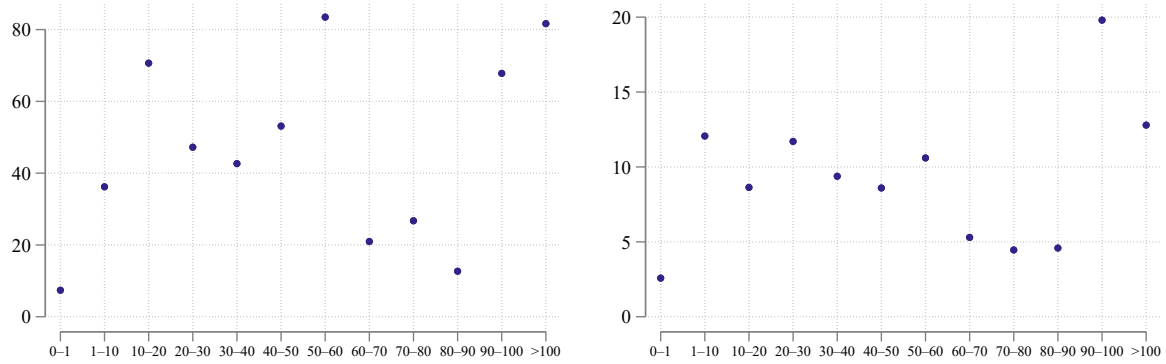

[88] Strictly speaking, this holds for given route costs, which change when we recalibrate the model.

Table F.1. Hub Rents in the Thought Experiment

Hub	Hub-Use Share (%)	Hub Rents (USD in M)	Export Gain (USD in M)	Change in Real Income (%)			
				With Hub Rents			Main Specification
				Total	Real Wages	Rents	
TUR	30.50%	1,028.5	1,799.6	0.189%	+0.021%	+0.168%	0.012%
BLR	19.56%	332.2	2,309.7	-0.570%	-0.979%	+0.409%	-0.976%
CHN	13.21%	265.3	16,345.5	0.006%	+0.005%	+0.001%	0.005%
ARE	7.82%	186.2	424.6	0.090%	+0.039%	+0.051%	0.038%
SRB	6.24%	41.5	485.9	0.159%	+0.073%	+0.086%	0.077%
IND	5.56%	58.2	1,617.5	0.006%	+0.003%	+0.002%	0.003%
THA	1.96%	9.0	788.8	0.009%	+0.008%	+0.001%	0.008%
ISR	1.87%	10.0	452.9	0.023%	+0.018%	+0.005%	0.019%
MYS	1.60%	1.9	602.6	0.007%	+0.007%	+0.000%	0.007%
MAR	1.54%	13.5	128.0	0.023%	+0.012%	+0.011%	0.012%

Notes. This table reports results from the thought experiment of Section 5, in which each hub charges the highest markup it can without losing the trade to a competing route, subject to the cap in equation (41), and the model is recalibrated so that it still matches the observed hubs and the estimated effects of the bans. All results refer to observed transshipment. Rows show the ten countries that most often serve as hubs in the thought experiment. "Hub-Use Share" is a country's hub share in the thought experiment, measured as in Section 4.3. Rents and export gains are in millions of 2019 USD. Export gains are the change in each hub's own exports to Russia relative to the baseline without sanctions, summed across all products. These goods originate in the hub itself, whereas rerouted coalition goods keep their coalition origin and are not included in this column. The columns under "With Hub Rents" report the change in real income, $(\hat{W}_h - 1) \times 100$, and split it into the change in real wages and the contribution of the rents, $100\,\hat{W}_h R'_h / X'_h$ percentage points, where X'_h is the hub's counterfactual expenditure. The split is exact within the model, as baseline rents are zero. The real-wage component still reflects the equilibrium effects of spending the rents. The last column reports the real-income change in the main specification, in which hubs earn no rents. Belarus is itself sanctioned throughout, which explains its real-income loss. The results are discussed in Section 5 and Appendix F.

G Additional Figures

(A) Unit Values (USD/kg) (B) Avg. Nr. Oth. HS6-Prod. per Shipment

Figure G.1. Evasion and Pre-War Characteristics of Export-Banned Products

Note: Bins are constructed over an evasion measure defined for each HS6 product as the ratio of its average monthly Russian imports of EU-origin products in the post–export-ban period (August 2022–December 2024) to the corresponding average in 2019. The sample consists of the 668 HS6 products fully subject to EU export bans by July 2022. Each point reports the unweighted mean of the characteristic shown on the y-axis within a bin of the evasion measure, except for unit values, which are reported as medians within bins. All product characteristics refer to 2019.

H Additional Tables

Table H.1. Robustness of the Main Results

Specification	Real-Income Loss		Relative Transshipment Gain	Decline in Fully Banned Imports
	OT	NT		
Main specification	1.26%	1.66%	32%	76%
$\nu = 0.5$	1.26%	1.67%	32%	76%
$\nu = 0.9$	1.26%	1.66%	32%	76%
$\nu = 2.2$	1.25%	1.66%	32%	76%
$\sigma_M = 1.2$	1.26%	1.67%	32%	76%
Home-share floor 5%	1.24%	1.70%	37%	75%
Hub shares from re-exports	1.28%	1.67%	31%	76%
Wartime demand ($\hat{\alpha}_R^M = 3$)	1.32%	1.72%	31%	78%
Trade elasticities halved	2.29%	2.92%	28%	78%

Notes. This table compares the main results with alternative parameter choices and an alternative hub-share target. The first two columns report Russia's real-income loss in percent under observed transshipment (OT) and no transshipment (NT), and the third column the increase in the NT loss in percent of the OT loss (the relative transshipment gain). The last column reports the decline in Russia's imports of fully banned coalition-origin products under OT, measured as the percentage change in their share of world expenditure. The main specification sets $\nu = 1.1$, $\sigma_g = 2.2$ for all groups, and a 10% floor on home shares. Except for the wartime-demand exercise, each specification recalibrates the hub wedges and the partial-ban cost increase, as in Section 4.3. "Hub shares from re-exports" calibrates the relative hub wedges to re-exports only, whose hub is the recorded dispatch country. "Wartime demand" triples Russia's demand weight for the military-relevant group, holding the calibrated hub wedges and the partial-ban cost increase fixed. Its losses are measured against the no-sanctions equilibrium of this economy. "Trade elasticities halved" scales the trade elasticities θ^k by one half, leaving the calibrated demand system unchanged. To keep every θ^k above $\sigma_{g(k)} - 1$ (Appendix E.1), the halved elasticities are floored at $(\sigma_{g(k)} - 1) + 0.1$, which binds for 227 products. The results are discussed in Section 5.

Table H.2. Robustness of Group-Level Real Absorption

	Decline in Real Absorption (%)					
	Observed Transshipment			No Transshipment		
Specification	M	C	O	M	C	O
Main specification	3.6%	2.0%	0.9%	4.0%	2.7%	1.1%
$\nu = 0.5$	2.4%	1.6%	1.1%	2.8%	2.1%	1.4%
$\nu = 0.9$	3.2%	1.8%	1.0%	3.6%	2.5%	1.2%
$\nu = 2.2$	6.0%	2.6%	0.5%	6.4%	3.7%	0.6%
$\sigma_M = 1.2$	3.7%	2.0%	0.9%	4.2%	2.7%	1.1%
Home-share floor 5%	3.6%	1.9%	0.9%	4.1%	2.7%	1.2%
Hub shares from re-exports	3.7%	2.0%	0.9%	4.0%	2.7%	1.1%
Wartime demand ($\hat{\alpha}_R^M = 3$)	3.6%	1.9%	0.9%	4.0%	2.7%	1.1%
Trade elasticities halved	6.6%	3.5%	1.6%	7.7%	4.6%	2.0%

Notes. This table reports the decline in Russia's real absorption, $(1 - \hat{Q}_R^g) \times 100$, of military-relevant ($M$), other critical ($C$), and remaining goods ($O$), under observed transshipment and without transshipment, for every specification of Table H.1. Real absorption includes domestic supply. The specifications are described in the notes to that table. Group-level real absorption is defined in Section 4.2.4. The results are discussed in Section 5.

Table H.3. The Effects of the Sanctions on EU Member States

Country	Baseline Exports of Fully Banned Products (USD in M)	Change in Exports to Russia (%)						Change in Real Income (%)

Notes. This table extends Table 3 to the individual member states. The first column reports baseline exports of fully banned products to Russia in millions of 2019 USD. Export changes are relative to the corresponding baseline flows of fully banned (Full), partially banned (Partial), and all products (Total), under observed transshipment (OT) and no transshipment (NT). Real-income changes are $(\hat{W} - 1) \times 100$. In the EU27 row, the export changes refer to flows summed over member states, while the real-income entries are medians across member states, as in Table 3. The results are discussed in Section 5.
